THIS INDEX to *Public Health Reports* and Public Health Monographs is divided into a subject index and an author index.

The subject index carries one or more entries for each item published. In addition to the subject headings, categorical headings include ANNOUNCEMENTS (divided into EXAMINATIONS, ORGANIZATIONS, and PERSONNEL), CONFERENCE REPORTS, DEATHS, FILMS, FRONTISPIECES, GRANTS AND FELLOWSHIPS, LEGAL NOTES, PUBLICATIONS, PUBLIC HEALTH MONOGRAPHS, and TRAINING COURSES.

Public Health Monographs published concurrently with *Public Health Reports* in 1957 are listed in numerical order under that category heading. The monograph summaries appearing in the journal are indexed under appropriate subject headings.

One asterisk before the page number indicates an original, signed article. The sign of two asterisks, used only in the author index, indicates a monograph. Entries without any symbol may refer to summaries or briefs of papers presented at conferences, narrative conference reports, statements or reports of committees, short reports without authors, or similar items.

Illustrative material on the inside of the front cover of each issue is indexed by month under the heading FRONTISPIECES. It is recommended, therefore, that the covers be included in a bound volume.

A compiled annual list of Public Health Service publications may be obtained from the Public Inquiries Branch, Office of Information.

The National Health Survey Act

WITHIN A FEW MONTHS, the Public Health Service will begin a survey of the health of the American people. On July 3, 1956, the President signed into law a bill authorizing a continuing survey of disease, injury, impairment, and disability in the United States. The program, located in the Division of Public Health Methods, will include a series of special studies to collect other detailed morbidity data and additional studies to evaluate the methods used in the survey.

Historical Background

Twenty-one years ago last September, the last effort to obtain comprehensive statistics on illness in the general population was getting under way. The National Health Survey of 1935-36 was a tremendous undertaking in which interviewers visited 737,000 urban households to find out which members of the household had experienced disabling illness and which had specified chronic diseases or impairments.

In the years since the 1935-36 survey its findings have formed the basis for more than 200 reports, articles, and comparative studies. Even in recent years the urban statistics from that survey, generalized to the country as a whole and adjusted for population changes, have provided the only available estimates of the prevalence of many important diseases.

Although the National Health Survey of 1935-36 was by far the largest study ever devoted to learning the facts of illness and injury in the general population, it was not the first of its kind in this country. A number

of smaller studies had demonstrated that the interview method can provide useful information about the amount and distribution of disease, the circumstances of injury, the loss of time from work or other usual activities resulting from disease and injury, and the utilization of medical care in connection with morbidity. Best known of these are the Hagerstown, Md., studies of the early 1920's and the survey made during the years 1928-31 by the Committee on the Costs of Medical Care.

The smaller, community-type studies continued after 1936, and additional refinements were made in the techniques. An important example of an intensive community study is the Eastern Health District Study conducted in Baltimore by the Public Health Service and the Milbank Memorial Fund in the years 1938-43.

At the same time, great advances were made in the science of population sampling, with the Bureau of the Census leading the way in the development of practical methods for applying the theory of probability sampling in the field. In 1943 the Census Bureau, building upon an earlier survey by the Works Progress Administration, began to collect information on the labor force by conducting interviews each month in a national sample of households. Now known as the Current Population Survey, that survey, almost from its start, was used to satisfy some of the growing demand for national morbidity statistics by adding, from time to time, questions on illness to the basic questionnaire. As recently as September 1956 the Current Population Survey carried a supplement dealing with the utilization of hospital care.

Neither the intensive community studies nor the occasional limited data supplied by adding questions to the Current Population Survey

Linder to Direct Program

Forrest E. Linder, Ph.D., has been named director of the National Health Survey Program of the Public Health Service. The new program will use scientific sampling techniques to survey the nature and extent of illness and disability in the population each year.

Formerly deputy chief of the National Office of Vital Statistics of the Public Health Service, Dr. Linder returns to the Service from the United Nations Statistical Office, where he was chief of the demographic and social statistics branch. During World War II he had technical responsibility for the reorganization of the medical statistics of the Navy.

were capable of filling the increasing needs. Public health programs, both public and private, and health insurance plans, medical research efforts, and programs to conserve manpower were increasing in scope. A broader statistical base was needed for the planning and evaluation of these programs.

Furthermore, the national data collected in 1935 and 1936 were becoming increasingly inappropriate as descriptions of the current health of the population as a whole. Two wars, the "wonder" drugs, returning prosperity, and a great increase in the proportion of the population covered by hospitalization insurance brought changes whose effect on morbidity could not be measured. Overweight, smoking history, exposure to air pollution, and other aspects of the environment scarcely touched on in the earlier surveys had become significant factors in epidemiology.

The National Committee

In January 1949 the United States National Committee on Vital and Health Statistics was established. Recognizing the obsolescence of the existing data, the committee gave immediate attention to the problem of obtaining adequate national morbidity statistics. Two successive ad hoc subcommittees were set up by the chairman of the national committee "to frame the problems in morbidity statistics, including

chronic diseases and medical care statistics, in order that morbidity data may be directly related to demographic factors." These subcommittees recommended study of a number of methodological questions, but, even as the recommendations were being made, steps were being taken in several parts of the country to get some of the answers in community surveys. About the same time a bill calling for an 18-month study of methods of measuring illness passed the Senate but failed of passage in the House of Representatives.

Within the next few years, sample surveys of illness were initiated in New York City, in San Jose, Calif., in Hunterdon County, N. J., and in Pittsburgh. Every one of these, as well as later surveys in Baltimore, Kansas City, and in the State of California contributed to the knowledge of how such data collection can be made more accurate and useful.

Anticipating the solution of the methodological problems raised in the ad hoc subcommittees, the chairman of the national committee, in February 1951, established the Subcommittee on National Morbidity Survey and charged it with the drafting of "a plan for a national morbidity survey keeping in view the interests of local areas." It was the report of this group that led to the proposal for specific legislative authorization for a continuing national program. This report (1), which is the basis for the present National Health Survey, contains a valuable list of the major applications of morbidity statistics. These are given on page 3.

Provisions of the Act

The Department of Health, Education, and Welfare proposed in the summer of 1955 legislation specifically authorizing the Surgeon General of the Public Health Service to conduct a continuing survey of illness and disability in the Nation. A bill was drafted, made part of the President's legislative program on health matters, and introduced in both houses of Congress in February 1956. The few amendments added tended to strengthen the bill (2, 3), which passed the Senate in March and the House of Representatives in June. The Senate concurred in the House changes, and on

Uses for Morbidity Statistics

Administrative planning: Statistics on the incidence and prevalence of illness and accidental injury and the resulting disability are used as a guide to administrative planning and the evaluation of public health programs. Illustrative applications of morbidity and disability statistics include the ranking of public health problems in order of importance and the determination of how resources should be divided among various programs; checking the adequacy of notifiable disease reporting; and analyzing trends of specific diseases to evaluate the effect of preventive and therapeutic innovations.

Manpower problems: Another application of morbidity statistics, particularly those providing measures of disability, is in the field of manpower problems. To estimate the economic loss to industry resulting from morbidity, information on absenteeism owing to disease and injury is required. Data on the numbers of persons with chronic diseases and handicapping conditions, and the employment status of such persons, will permit estimates of potential additions to the labor force. Statistics on the sickness rates of handicapped persons, as compared with the nonhandicapped, would be useful to industry and the armed services.

Industrial use: The pharmaceutical and appliance industries have an interest in statistics in order to estimate the markets for particular preparations and appliances. Such information should include data on the utilization of medical services of various types, for example, the frequency of particular operations and of prescriptions and the use of hearing aids and artificial limbs.

Health education: Accident prevention agencies require estimates of the national incidence of accidental injuries, by type and degree of disability. Estimates of the prevalence of cerebral palsy, multiple sclerosis, blindness, deafness, and many other diseases and impairments are needed by voluntary health agencies concerned with these conditions.

Provision of health services: Morbidity data are often used as the basis for estimates of the needs for hospital facilities, nursing home beds, home care programs, or other types of facilities or services. Such information may be used to estimate the number of persons requiring rehabilitation services, to help in planning the extension of the scope of medical care insurance, and for similar estimates in the field of medical care.

Medical research: While morbidity statistics from surveys of the general population are not suitable for making conclusive tests of hypotheses in medical research, they can be useful in suggesting hypotheses for further testing. For example, information on the association between the incidence or prevalence of various diseases and demographic factors, such as age, sex, marital status, occupation, and economic status, may point the way for more intensive investigations. Likewise, data on the geographic distribution of diseases will sometimes provide clues to their causes.

—Excerpts from *“Proposal for Collection of Data on Illness and Impairments: United States,”* report of Subcommittee on National Morbidity Survey, United States National Committee on Vital and Health Statistics.

July 3 the President signed the bill. In late July, Congress appropriated funds for the first fiscal year of operation.

The major provisions of the National Health Survey Act follow.

“(a) The Surgeon General is authorized . . . to make, by sampling or other appropriate means, surveys and special studies of the population of the United States to determine the extent of illness and disability and related information . . . and . . . in connection therewith, to develop and test new or improved meth-

ods for obtaining current data on illness and disability and related information.

“(b) The Surgeon General is authorized, at appropriate intervals, to make available, through publications and otherwise . . . the results of surveys or studies made pursuant to subsection (a).

“(c) For each fiscal year . . . there are authorized to be appropriated such sums as the Congress may determine for carrying out the provisions of this section.

“(d) To assist in carrying out the provisions

of this section the Surgeon General is authorized and directed to cooperate and consult with the Departments of Commerce and Labor and any other interested Federal departments or agencies and with State health departments. For such purpose he shall utilize insofar as possible the services or facilities of any agency of the Federal Government and . . . of any appropriate State or other public agency, and may . . . utilize the services or facilities of any private agency, organization, group, or individual, in accordance with written agreements . . ."

Public Law 652 is in the form of an amendment, as section 305, to the Public Health Service Act of 1944 (Public Law 410, 78th Cong.). It also amends another section of the basic act by authorizing the Surgeon General to "make available, to health officials, scientists, and appropriate public and other nonprofit institutions and organizations, technical advice and assistance on the application of statistical meth-

ods to experiments, studies, and surveys in health and medical fields." In addition it is important to note that Public Law 652 provides that information collected under the authority of the act is to be obtained "on a non-compulsory basis."

Knutson 1957 APHA President

Dr. John W. Knutson. Assistant Surgeon General and chief dental officer of the Public Health Service since 1952, is president of the American Public Health Association for 1957. He succeeds Dr. Ira V. Hiscock of Yale University.

Dr. Knutson first joined the Public Health Service in 1931. He was assigned to the States Relations Division in 1944 as chief of the Dental Section and later served as chief of the Division of Dental Public Health.

He was chairman of an international group of consultants convened in Geneva in 1954 by the World Health Organization prior to the

establishment of a permanent program of dental health. Long active in the Federation Dentaire Internationale, he is vice president of its Commission on Public Dental Health Services and chairman of the Subcommittee on Statistics. In 1955 Dr. Knutson joined the WHO staff for 6 months to organize its dental program.

He is a diplomate and founding member of the American Board of Dental Public Health, and since 1948 has been instructor in dental public health in the School of Dentistry, Georgetown University. Dr. Knutson is an editor of the Year Book of Dentistry and a contributing editor of Dentistry in Public Health by Pelton and Wisan. He is also the author of a number of reports on dentistry.

Organization of National Health Survey

THE THREE TYPES of activity authorized in the National Health Survey Act have as their purpose the obtaining of "accurate and current statistical information on the amount, distribution, and effects of illness and disability in the United States and the services received for or because of such conditions" (1). These three activities—a sample survey of the population, a series of special studies, and the development and testing of new or improved methods for obtaining current data—constitute the National Health Survey Program. To plan and direct the program, a small, experienced staff is being recruited in the Division of Public Health Methods of the Public Health Service.

The nucleus of the staff is already at work, drafting plans to implement the act. Successful execution of the program will require the assistance of health departments, the medical and dental professions, hospitals, and many other sources of health information. It is the understanding and cooperation of the general public, however, that is the most important ingredient of success.

The Bureau of the Census is providing expert help in designing the sample survey of the population. Technical consultants will give advice on all methodological aspects of the program. Three advisory committees will review the plans, keep the staff informed of needs for statistics which the program is capable of filling, and advise on obtaining the cooperation of professional groups and the public. One advisory committee will be drawn from operating agencies within the Department of Health, Education, and Welfare. A second committee will comprise representatives of all Federal departments and agencies having an interest in the data to be supplied.

*Prepared by the Division of Public Health Methods,
Office of the Surgeon General, Public Health Service.*

The third committee will be made up of leaders from the professions and business and from State and local governmental fields.

In addition to these consultants and committees, the program staff will have frequent discussions with individual agencies and groups about ways in which the program can be made more useful.

Planning for the three phases of the National Health Survey Program is now going on. First priority is being given to setting up the sample survey of the population. Methodological studies are, of course, an essential part of the planning process and will continue throughout the program since improving the techniques and adding to the usefulness of the results should never be considered to be complete. Collection of data for the series of special studies will not begin until after the sample survey is under way.

Despite the fact that decisions on various points are not yet final, it is possible to describe now, in general terms, the plans for the program.

The Household Survey

The sample survey phase of the program will consist of a continuous sampling of households on a national basis. Information will be collected in each household by carefully trained and supervised interviewers. The Bureau of the Census is devising sampling and field interviewing plans and preparing instruction and training manuals. The bureau will hire and train interviewers, supervise the field work, edit and code the questionnaires, and produce the required tabulations. The Public Health Service is responsible for the content of the survey questionnaire, for content of the tabulations that will be made of the replies, and for the analysis and publication of the results.

Field work on the household survey will start

with pretesting activities on a small scale in early 1957. A "dry run" on a national scale will follow later in the spring. Collection of statistical information for periodic publication will begin about July 1.

The Questionnaire

When the household survey is in full operation, the questionnaire for the interview will consist of two parts, core items and supplements. Core items will include only the most basic types of information and will remain on the questionnaire for a long period of time. During the dry run period of the survey, only core items will be on the questionnaire.

The core questionnaire, as presently planned, will provide information on the incidence of illnesses and injuries involving either medical care or loss of time from usual activities (for example, the number of days lost from work or school), or both. The prevalence of chronic conditions known to the family and of various types of impairments will be obtained to the extent that they have caused trouble for the individual within a year preceding the interview. Persons with chronic conditions will be classified according to the degree to which these conditions have limited their activities.

In addition, core questions will ascertain the number of visits to physicians and dentists and the number and duration of hospital stays as well as the number of operations performed while the family member has been in the hospital.

These various measures of illness, disability, and medical care will be classifiable, on the basis of information collected in the core questionnaire, by age, sex, race, marital status, educational attainment, income, occupation, and industry for those in the labor force, by usual activity for those not in the labor force, and by residence in farm and nonfarm areas. The illness will also be classifiable by diagnosis in broad groups and by physician attendance.

After the dry run, the questionnaire will be opened for special supplementary inquiries. In this way, flexibility in content can serve the interests of additional users of the data. The supplements may be repeated at regular intervals or may be included once only. Since the total amount of interviewing in any one month

will be relatively small, supplements may remain on the questionnaires for 3 months or longer depending on the degree of geographic detail required.

Collection of Data

Initially, the sample of households will be selected within the 330 areas (counties, parts of counties, or metropolitan areas) that constitute the first stage of sampling for the Current Population Survey of the Census Bureau. The Current Population Survey has for some years been collecting information, from a national sample each month, on employment, unemployment, and other economic data. Except very rarely, and then by chance, the households interviewed for the National Health Survey will not be the households sampled in the Current Population Survey.

After the dry run, which has as its major purpose the establishment of smoothly operating procedures, the household survey will be expanded gradually over a 6-month period until it includes approximately 400-450 sample areas known as primary sampling units. The reason for this difference in the design of the two national samples is that the National Health Survey will require estimates in greater geographic detail than the Current Population Survey.

The number of interviews in the primary sampling units will be far fewer than in the Current Population Survey. The interview rate during the dry run will be approximately 3,000 households a month for the country as a whole. By the end of 1957 it is hoped to increase the rate to about 3,500 households a month. This is in contrast to the 35,000 households interviewed each month in the Current Population Survey.

A careful control on the quality of the interviewing will be maintained by a regular program of reinterviews, and other devices, in a subsample of the households.

Publication of Data

The present plan is periodically to publish separate morbidity statistics for each of nine standard metropolitan areas: New York, Chicago, Los Angeles, Philadelphia, Detroit, San Francisco, Boston, Pittsburgh, and the com-

bined Washington, D. C.-Baltimore area. In addition, separate statistics will be published periodically for each of 11 geographic regions of the country. These correspond to the 9 standard geographic "divisions" of the Census Bureau, except that the East North Central Division and the South Atlantic Division each will be divided into two parts. Data from the regions will be shown separately for large metropolitan areas as a group, all other urban areas as a group, and rural areas.

To publish statistics in this maximum geographic detail, it will be necessary to accumulate data for a period of 2 years. However, summary statistics may be presented at more frequent intervals for four major Census Bureau regions of the country (Northeast, North Central, South, and West) as well as by size of place, in terms of population, for the country as a whole.

According to present plans, the most frequent publication of any particular statistical table will be at intervals of 3 months. Data for the preceding calendar quarter will be included. These published tables will be devoted to information for which it is desirable to show quarter-to-quarter change. An example might be the frequency of injuries resulting from automobile accidents.

Special Studies

The special studies will produce auxiliary information of a type that the household interview cannot provide. They will be based either on subsamples of the national household sample or on separate samples. Though they may vary in nature, all special studies will be based upon scientifically designed samples so that the results can be generalized to a defined population. They will emphasize the measurement of disease by means of clinical tests, physical examinations, or the analysis of medical records. The entire health survey program is planned as an integrated system in which the special studies will supplement the data obtained in household interviews.

Because of wide interest in the prevalence of chronic diseases and impairments, including conditions not yet diagnosed, the first of the special studies will be designed to provide a

thorough medical and dental evaluation by a professional team for a cross-sectional sample of persons of all ages. The need for statistics on undiagnosed and nonmanifest conditions has been emphasized by the Subcommittee on National Morbidity Survey (2). Two recent surveys, one in Hunterdon County, N. J., and one in Baltimore, have demonstrated that, in conjunction with a household interview survey, the medical evaluation of a subsample can produce useful data.

The staff of the National Health Survey Program will conduct the studies with the help of field personnel employed for each study. Part of the work, however, such as the abstracting of medical records, may be contracted to organizations with access to the information needed.

Although first priority is being given to the household survey, staff and consultants of the program have begun to design the first of the special studies for the National Health Survey. Field work on this study, however, probably will not begin before late 1957.

Methodological Studies

The third phase of the program will include methodological experiments in connection with the national household survey; studies to determine the nature and magnitude of errors of measurement associated with clinical tests and physical examinations; matching of data from one source against data from another; and basic investigation of entirely different methods of measurement, such as panels of physicians keeping records concerning the patients under their care.

The methodological studies will be conducted sometimes alone by the staff of the National Health Survey Program, and at other times in conjunction with the Bureau of the Census or other organizations. Some methodological problems may be investigated by schools of public health, health departments, health insurance agencies, or research groups employed on a contract basis.

Limitations of the Program

"It is clear that this legislation would close a major gap in our population and health sta-

with pretesting activities on a small scale in early 1957. A "dry run" on a national scale will follow later in the spring. Collection of statistical information for periodic publication will begin about July 1.

The Questionnaire

When the household survey is in full operation, the questionnaire for the interview will consist of two parts, core items and supplements. Core items will include only the most basic types of information and will remain on the questionnaire for a long period of time. During the dry run period of the survey, only core items will be on the questionnaire.

The core questionnaire, as presently planned, will provide information on the incidence of illnesses and injuries involving either medical care or loss of time from usual activities (for example, the number of days lost from work or school), or both. The prevalence of chronic conditions known to the family and of various types of impairments will be obtained to the extent that they have caused trouble for the individual within a year preceding the interview. Persons with chronic conditions will be classified according to the degree to which these conditions have limited their activities.

In addition, core questions will ascertain the number of visits to physicians and dentists and the number and duration of hospital stays as well as the number of operations performed while the family member has been in the hospital.

These various measures of illness, disability, and medical care will be classifiable, on the basis of information collected in the core questionnaire, by age, sex, race, marital status, educational attainment, income, occupation, and industry for those in the labor force, by usual activity for those not in the labor force, and by residence in farm and nonfarm areas. The illness will also be classifiable by diagnosis in broad groups and by physician attendance.

After the dry run, the questionnaire will be opened for special supplementary inquiries. In this way, flexibility in content can serve the interests of additional users of the data. The supplements may be repeated at regular intervals or may be included once only. Since the total amount of interviewing in any one month

will be relatively small, supplements may remain on the questionnaires for 3 months or longer depending on the degree of geographic detail required.

Collection of Data

Initially, the sample of households will be selected within the 330 areas (counties, parts of counties, or metropolitan areas) that constitute the first stage of sampling for the Current Population Survey of the Census Bureau. The Current Population Survey has for some years been collecting information, from a national sample each month, on employment, unemployment, and other economic data. Except very rarely, and then by chance, the households interviewed for the National Health Survey will not be the households sampled in the Current Population Survey.

After the dry run, which has as its major purpose the establishment of smoothly operating procedures, the household survey will be expanded gradually over a 6-month period until it includes approximately 400-450 sample areas known as primary sampling units. The reason for this difference in the design of the two national samples is that the National Health Survey will require estimates in greater geographic detail than the Current Population Survey.

The number of interviews in the primary sampling units will be far fewer than in the Current Population Survey. The interview rate during the dry run will be approximately 3,000 households a month for the country as a whole. By the end of 1957 it is hoped to increase the rate to about 3,500 households a month. This is in contrast to the 35,000 households interviewed each month in the Current Population Survey.

A careful control on the quality of the interviewing will be maintained by a regular program of reinterviews, and other devices, in a subsample of the households.

Publication of Data

The present plan is periodically to publish separate morbidity statistics for each of nine standard metropolitan areas: New York, Chicago, Los Angeles, Philadelphia, Detroit, San Francisco, Boston, Pittsburgh, and the com-

Supply, Distribution, and Use of Poliomyelitis Vaccine

By JACK C. HALDEMAN, M.D.

WITH THE ANNOUNCEMENT of the successful results of the 1951 field trials of Salk poliomyelitis vaccine, the way was opened to prevention and control of one more communicable disease.

The extraordinary progress achieved in this past year and a half in providing at least partial immunization to the most susceptible population is a tribute to the working partnership of the medical and pharmaceutical professions, local, State, and Federal governmental agencies, voluntary agencies, the drug manufacturers, and individual citizens. Together, they have labored diligently to insure the most equitable possible distribution and use of the limited amount of vaccine available.

The purpose of this article is to review the results of this cooperative effort and to outline the course that lies ahead for provision of maximum protection against poliomyelitis for the total population.

Supply and Distribution

We are no longer faced with the problem of short supply of vaccine. The voluntary system of Federal allocation of vaccine, which was

adopted as the most equitable method for distribution of a scarce product, was terminated on August 1, 1956. Decontrol of vaccine was made possible by the following sequence of events.

Vaccine production had built up slowly through 1955 and the early months of 1956, but releases during April, May, and June brought the supply up to the demand level in a number of States. By July 27, 1956, more than 85 million cubic centimeters of vaccine had been released. Since there are approximately 65 million persons in the group most susceptible to poliomyelitis in this country (persons 0 through 19 years of age and expectant mothers), enough vaccine was now available to provide two injections for 70 percent of those eligible to receive it.

Because of State variations in immunization programs and the more plentiful supply of vaccine, a number of States did not request their shares of vaccine released during late June and July 1956. This necessitated reallocation of their shares to those areas of the country where demand still exceeded available supply. For these reasons, it was decided that the needs of all areas could best be met by releasing vaccine through normal distribution channels rather than through the Federal system of allocation to the States.

Since Federal decontrol of vaccine, an additional supply of more than 28¾ million cubic centimeters has been released. All parts of the country now appear to be able to get as much vaccine as they need.

Termination of the allocation system does not affect the allotment of Federal funds avail-

Dr. Haldeman is chief, Division of General Health Services, Bureau of State Services, Public Health Service, Washington, D. C. His paper is based on a talk he gave before the 25th annual meeting of the American Academy of Pediatrics, New York City, October 11, 1956. Figures have been revised as of November 15, 1956.

tistics. We have available today only piecemeal data—from special studies and surveys, from reports on particular kinds of diseases, or from records kept for a variety of purposes on particular segments of the population" (3).

"A national health survey based on a representative sample of the total population would provide a comprehensive picture of illness, both with respect to coverage of the population and to inclusion of the entire range of types of illness. As such it will supplement and extend existing sources of health data" (4).

These statements appeared in the Senate and House of Representatives reports on the proposed national health survey. However, recognition of the potential value of the survey in defining more clearly the extent of illness and disability in the Nation should not obscure the fact that the program has definite limitations.

The size of the national sample, for example, is such that estimates in greater geographic detail than planned cannot be made without enlarging the sample for that purpose. Moreover, the sample cannot provide independent information concerning persons in small groups of the population or for diseases of low frequency.

Further, there are limitations to the accuracy of diagnostic information collected in household interviews. The household respondent, at best, can pass on to the interviewer only the information the physician has given to the family. For conditions not medically attended, diagnostic information is often no more than a description of symptoms. Facts concerning the circumstances of the illness or injury and the resulting action taken by the individual, such as going to bed or seeing a physician, can be obtained more accurately from household members than from any other source. However, when clinical detail or diagnoses for unattended or nonmanifest illness are required, information procured by interview does not substitute for a medical examination. For this reason, information collected in the special studies, for example, by physical examinations and clinical tests, will supplement the results from the household survey.

The statistics from the program will not provide critical tests of clinical and epidemiological hypotheses. For example, the program could not test the hypothesis that a specific vaccine would prevent a certain disease. For this, an experimental design, a control group, and similar conditions would be required. The program may, however, suggest hypotheses that can be tested by other appropriate means. Information that is required quickly for corrective action, as in an epidemic, will have to come from other sources, such as the notifiable disease reporting system.

The program is intended to supplement existing sources of information and provide a background of broadly based illness statistics. It does not purport to replace the many ad hoc studies now being conducted.

Aside from such limitations as these, imposed by the methods to be used and the resources available, the program is free to collect any statistics on the incidence, prevalence, or other measures of disease, injury, or impairment, the disability or other effects of this morbidity, and the medical care used in its treatment. The sole guide is the usefulness of the data.

Prompt Use of Poliomyelitis Vaccine

Secretary Folsom's report on the Salk poliomyelitis vaccine deserves the attention of every young adult, of every parent, in America.

The supply of vaccine is now plentiful.

I join with Secretary Folsom, the Surgeon General of the Public Health Service, and the National Foundation for Infantile Paralysis in urging that the vaccine be used promptly before the next poliomyelitis season arrives.

DWIGHT D. EISENHOWER
President of the United States
November 28, 1956

Opportunity Ahead

Knowing of your interest in the poliomyelitis vaccination program I am making this report on developments to date and on a great opportunity which lies ahead.

Millions of children who have so far received only 1 or 2 injections should, before next summer, be given the additional protection provided by the recommended 3 doses. The full benefit of the vaccine is achieved only with 3 injections.

Millions of young adults, as well as children who have had no vaccine at all so far, should now begin their vaccinations in order to receive the full three doses before next summer's peak of poliomyelitis incidence. All States have now made commercial supplies of the vaccine available to adults.

Prompt use of the vaccine—this is our problem and opportunity now. And this will require the earnest and vigorous cooperation of parents, physicians, schools, officials at all levels of government, and public and private health agencies.

Through prompt use of increasing supplies of vaccine, the Nation can go a long way, next year, toward elimination of this dread disease.

The National Foundation for Infantile Paralysis has recognized the need for prompt action and is presently engaged in a vigorous campaign to urge that all unite in this cause—the cause of preventing needless illness.

Since the vaccine was approved for public use—some 18 months ago—about 115 million cc's. or doses, have been released by the Public Health Service. More than \$53 million in Federal funds have been made available to help pay for vaccine for children and expectant mothers.

The results have been extremely encouraging.

Surveys show that among children vaccinated with only one or two doses, the incidence of paralytic poliomyelitis has been reduced about 75 percent. We can expect an even greater reduction as more and more persons receive three injections.

I know you share my gratification at the great progress that has been made, and my hope that the people of the Nation will take full advantage of this opportunity to protect their children and themselves against the ravages of poliomyelitis.

—From a report to the President,
by MARION B. FOLSOM, *Secretary*
of Health, Education, and Welfare.

able to the States for the purchase of poliomyelitis vaccine and the administration of public vaccination programs for children under 20 and expectant mothers. These funds, made possible by the Poliomyelitis Vaccination Assistance Act and amounting to \$53,600,000, will be available until June 1957. As of November 15, 1956, \$34,649,454 had been paid to the States and Territories.

Safety and Effectiveness

The early confidence we had with respect to safety and effectiveness of the vaccine has been reinforced by experience in its use to date.

Since May 1955, when vaccine was first released under revised safety standards, there has been no epidemiological evidence that any case of poliomyelitis has been causally related to the use of poliomyelitis vaccine. This reassuring conclusion is drawn from the study of data in which each reported case of poliomyelitis is related to the lot number of vaccine used, date and site of injection, site of first paralysis, and dates of onset of the disease and of paralysis.

Epidemiological studies conducted by 22 States and New York City during the 1955 poliomyelitis season showed that the paralytic attack rate among the unvaccinated children was consistently higher than among the vaccinated. Further studies in 1955 revealed that only among 7- and 8-year-old children, those for whom the vaccine had been used almost exclusively that year, was there a sharp lowering of paralytic attack rates. Thus, the 1955 experience reaffirmed the confidence in poliomyelitis vaccine established by the 1954 field trials.

Because of a continuing higher rate of vaccination throughout the current poliomyelitis season, completely comparable studies, yielding quantitative estimates of vaccine effectiveness, will not be possible. Therefore, characteristics of the current incidence are being studied to determine any changes attributable to the vaccine. Preliminary reports from a number of States in 1956 revealed that vaccinated cases comprise a low proportion of the total paralytic cases. Furthermore, in every age group the proportion of cases that are paralytic is greater among nonvaccinated cases than among the vaccinated.

The weekly incidence of poliomyelitis for the current year (1956) has been running at a lower level than in any year since 1947. The number of cases reported so far this year is about half the past 5-year average. Except for the severe outbreak in Chicago, only Louisiana and Utah have reported high incidence. California reported moderate incidence. Occurrence in most of the remaining States has been exceedingly low. From the national incidence figures alone, it is not possible to attribute this entire decrease to the vaccine. However, the studies mentioned strongly support the conclusion that the reduction is at least partially due to the vaccine. If we can achieve a high level of vaccination coverage, we should be able to conquer poliomyelitis.

Although poliomyelitis vaccine is now being used throughout the country, there has been considerable discussion about the use of vaccine during the season of high incidence, particularly in areas where epidemic conditions prevail. This discussion centers around the balance between the benefits of vaccination and the quantitative importance of the provoking effect of vaccinations under such conditions. The ability of immunizing injections of diphtheria, pertussis, and tetanus antigens, and of therapeutic injections such as penicillin, to provoke paralytic poliomyelitis has been reported by several authors. Consequently, before it was tried, there was some concern that poliomyelitis vaccine used during an outbreak of disease might show a similar ability to provoke paralysis.

Poliomyelitis vaccine was first used in an epidemic situation at a naval base in Hawaii in the fall of 1955. Although analysis of this program did not firmly establish the effectiveness of the vaccine in controlling an epidemic, incidence was lower in the vaccinated population. Moreover, a thorough evaluation failed to demonstrate any evidence of a provoking effect of the vaccine. During the first month after initiation of the mass vaccination program, incidence rates were identical in the vaccinated and unvaccinated populations. In the highly exposed family contacts of demonstrated cases, incidence was again similar in the vaccinated and unvaccinated contacts. However, examination of the clinical character of the vaccinated

if they are not being reached by other arrangements.

Unquestionably, high school programs will be needed to "step up" vaccination of teen agers. With schools now in session, there will undoubtedly be more active vaccination programs for adolescents.

Pediatricians have an excellent opportunity to urge young parents to seek immunization for themselves as well as for their children. The incidence of poliomyelitis among young parents is also high, and the degree of paralysis severe, often with tragic socioeconomic consequences. As with the adolescent group, very little preventive medicine is being practiced among these young adults since they have not yet reached the age where they are likely to be reporting regularly to a physician for physical checkups or for treatment of a chronic illness or disability.

Laboratory Diagnosis of Poliomyelitis

Relatively recent findings, which indicate that many diseases masquerade as poliomyelitis, have made physicians increasingly aware of the difficulty of diagnosing true poliomyelitis. It is now generally recognized that nonparalytic cases cannot be accurately diagnosed without laboratory tests. There is growing evidence that laboratory tests are equally important in diagnosing some paralytic cases.

The development of the poliomyelitis vaccine intensifies the need for laboratory confirmation of all cases of poliomyelitis and polio-like diseases. With widespread vaccination, the ratio of polio-like diseases to true poliomyelitis can be expected to increase. Also, the vaccine itself may modify the course of the disease, thus making the diagnosis on purely clinical grounds correspondingly more difficult. Furthermore,

if an accurate evaluation is to be made of the total and long-range effect of the vaccine, it is essential to identify, by laboratory testing, the type of poliomyelitis virus involved for all reported cases.

To provide such testing, a network of laboratories, especially equipped to analyze specimens taken from patients with poliomyelitis or polio-like diseases, has been organized by the Communicable Disease Center of the Public Health Service. The network includes a number of academic research laboratories and State health department laboratories.

Physicians are urged to use these facilities by sending specimens to their State health department or to whatever laboratory the department designates. Full cooperation by all physicians will not only aid in obtaining more accurate diagnoses but will also promote research and make possible a continuing evaluation of the effectiveness of the poliomyelitis vaccine.

Conclusion

In conclusion, the job immediately ahead is to continue immunizing as high a proportion of the susceptible population as possible. This will require the unrelenting effort of both physicians in private practice and members of the public health profession. Once a high level of protection has been attained, holding it over the years becomes our mutual objective. Unless this is done, sporadic outbreaks will continue to recur, as has been clearly demonstrated in the history of diphtheria control.

No group has a more important role in achieving full protection against poliomyelitis than the pediatricians of this country. More mothers are taking their children to pediatricians than ever before. Taking full advantage of this opportunity is a real challenge.

cases showed no predominance of paralytic disease, no concentration of cases 4 to 14 days after vaccination, nor any cases with first paralysis in the inoculated limb. In brief, the characteristics of provoked poliomyelitis were not present. Further, considering the extent of final paralysis in the paralytic cases which occurred within a month following vaccination, it was demonstrated that prior inoculation in an extremity did not increase the frequency of paralytic involvement of the extremity.

Thus, this report is reassuring because no measurable provoking effect could be found. But the study was based on only small numbers of cases.

The Chicago experience will provide an opportunity for further study of the use of vaccine during a serious outbreak—and on a larger population base. More than 1,000 cases of poliomyelitis occurred in Chicago in 1956, comprising more than 10 percent of the national incidence. Soon after the outbreak, a mass vaccination program was undertaken; more than a million doses of vaccine were given. The local health authorities, in cooperation with the Public Health Service, are intensively studying this outbreak. Particular emphasis is being given to evaluation of any evidence of a provoking effect. Although final conclusions cannot be drawn at this time, preliminary analyses have failed to reveal any such evidence so far.

Use of Vaccine

The amount of vaccine shipped into a State is a gross index of use since shipments are made only on bona fide orders which, for the most part, are promptly used.

In one State (Massachusetts) enough vaccine has been shipped to meet more than 65 percent of the total need for 3 injections for persons 0 through 19 years of age and expectant mothers; and in three more States (Illinois, Connecticut, and Utah) more than 50 percent. At the opposite end of the scale, less than 30 percent of the full amount needed has been shipped to 1 State and 1 Territory. Twenty-eight States and 3 Territories could meet between 40 and 50 percent of the need with the

vaccine already received, and 17 States and 2 Territories could meet between 30 and 40 percent. Of course, since many children and expectant mothers are not yet due for their third injections, these percentages are not indicative of the proportion of the priority group who have received some immunization. The figures do, however, indicate the dimensions of the job that remains to be done before the next poliomyelitis season.

Here, then, is the present challenge to the health profession, particularly to pediatricians, general practitioners, and public health physicians. This is still a new program as events in medical history are counted. Continuing educational efforts are required to impress parents with the importance of having their children immunized.

Several States are using some rather unique and interesting methods for stimulating an increase in the demand for vaccine. For example, the Mississippi State Board of Health employed 54 school teachers as "home visitors" for the summer to determine to what extent children in the families visited had been vaccinated and to inform the parents about the vaccination program and, particularly, where vaccinations could be obtained. This technique resulted in an immediate increase in immunizations both by physicians in private practice and by local health departments.

It is of interest to note that even though local health officials had extensively used radio, television, and newspaper publicity to announce the availability of the vaccine, the home visitors found that failure to take advantage of the program stemmed largely from ignorance of the availability of the vaccine or of the eligible age group.

Studies such as this help to pinpoint "soft spots" in educational campaigns, not only with respect to younger children under the supervision of pediatricians but also with respect to older children. The adolescent group is especially difficult to reach, falling in a sort of "never-never" land, too old to be seen regularly by the pediatrician and usually too young for regular visits to other medical practitioners. Perhaps the older siblings of the pediatrician's patients could be offered immunization

¹ Per patient maintenance expenditure was computed by dividing total maintenance expenditure by the average daily resident patient population in each State.

NOTE: These data are provisional and subject to change. Public hospitals include the State and county hospitals for mental disease and the psychopathic hospitals.

Mental Patient Data for Fiscal Year 1956

ON THE BASIS of summary data submitted to the National Institute of Mental Health of the Public Health Service by the various State and county mental hospital systems for fiscal year 1956, all categories show increases over the year 1955 except resident patients at the end of the year. This category shows a decrease on a national level for the second time in the history of the collection of such data. On the first such occasion, in 1913, there was a decrease of 0.3 percent.

| Item | 1955 | 1956 | Percent- age in- crease |
|--|---------------|---------------|-------------------------------|
| First admissions... | 122,391 | 126,510 | 3.4 |
| Readmissions..... | 55,626 | 59,521 | 7.0 |
| Discharges | 119,146 | 131,702 | 13.1 |
| Deaths in hospital.. | 44,400 | 48,478 | 9.2 |
| Resident patients at end of year... | 559,281 | 552,186 | -1.3 |
| Personnel em- ployed full time at end of year... | 145,462 | 152,439 | 4.8 |
| Maintenance expenditures: | | | |
| Total | \$618,229,797 | \$662,146,372 | 7.1 |
| Per patient... | \$1,112.81 | \$1,190.32 | 7.0 |

Figures shown for 1955 will not agree with those in the comparable report for 1955 (*Public Health Reports*, March 1956, pp. 214-215) since they are based chiefly on data submitted for the 1955 annual census of mental patients and, with the exception of two States, do not represent estimates.

Public mental hospitals were asked, on recommendation of mental hospital statisticians in their fifth annual conference, May 1955, to provide certain basic figures after the close of each year: first admissions, read-

missions, total discharges from the hospitals, and deaths in the hospitals during the year; average daily resident population; resident patients and total personnel employed full time at the end of the year; and total maintenance expenditures for patients (*Public Health Reports*, September 1955, pp. 905-909).

The National Institute of Mental Health made this survey in August 1956. It was realized that final and complete data might not be available because of variation in reporting procedures and fiscal year ending dates. Therefore, the hospitals were requested, if the answers to any or all of the items were unknown at the time of the survey, to enter their best estimates.

Reporting is complete for all hospitals queried. However, one county hospital in Tennessee could not supply financial data. The National Institute of Mental Health estimated maintenance expense for this hospital by applying the per patient maintenance expenditure for 1955 to the average daily number of resident patients reported for 1956. No other estimates were made by the institute.

It is interesting to note that in 1955, even though the survey was conducted one month later than in 1956, nine States were unable to report complete data whereas complete reporting was obtained for 1956. The estimates published for the 1955 survey compare closely with the final data for 1955 presented in the table. The percentage error in the estimates for each category follows: first admissions +1.1 percent; readmissions, -0.8 percent; discharges, -0.5 percent; deaths, +0.2 percent; resident patients, +0.2 percent; personnel, -0.3 percent; total maintenance expenditures, +0.7 percent and per patient expenditures +0.6 percent. In view of these small differences and the fact that all data for 1956 were supplied by the States, it is likely that these 1956 data are very close approximations to the final figures which will be available at a later date.

*Prepared by the Hospital Reports and Records Unit,
Current Reports Section, Biometrics Branch, Na-
tional Institute of Mental Health, Public Health
Service, Bethesda, Md.*

In western North America, the California little brown bat, *M. californicus*, is represented by four subspecies, which range from southern Alaska to southern Mexico. *M. californicus* is a small insectivorous bat of uncommon occurrence. Hall (2) found the species in Nevada hibernating in mine tunnels. Little is known of its habits or its distribution in Montana.

The second infected bat, identified as *Eptesicus fuscus pallidus*, was collected alive by a 10-year-old boy, who found it along with a dead bat on the floor of an unoccupied house in Hamilton. He adopted the bat as a pet, but the next day it died. When the child brought the dead animal to the laboratory, he was questioned carefully but denied having been bitten.

Information on *E. fuscus pallidus* is included in our 1955 report on chiropteran rabies (1).

The third infected bat, *Lasiurus cinereus cinereus*, was collected by one of us at Flathead Lake in northwestern Montana. As he was standing near the shore of the lake in open pine woods in bright daylight (6 p. m., August 18, 1955), his attention was attracted to a fluttering bat overhead. The bat flew in a direct line toward a large tree, which it struck without slackening flight. The animal fell to the ground, but it was conscious and squeaked when approached. He killed the bat with a light stick and kept it in a frozen food locker until it was taken to the laboratory.

The hoary bat, *L. cinereus cinereus*, is the largest of the bats found in the Pacific Northwest, but it is also a rather rare species. Its range includes almost the entire United States and southern Canada and northern Mexico. Davis (3) has recorded only a single specimen from Idaho. Dalquist (4), who mapped only seven collection records for the species in Wash-

Table 2. Characteristics of rabies virus after serial passage in mice

ington, states that information on the natural history of the hoary bat is meager. He further states that the hoary bat is migratory and leaves Washington in August and September to winter along the coast of central and southern California. Although *L. cinereus cinereus* is largely a forest-dwelling species, Durrant (5) writes, "I have taken specimens by shooting over desert water holes."

Some characteristics of the three isolates of rabies virus are noted in tables 1 and 2.

Although Negri bodies were found in microscopic sections of the brain of each of the three bats (table 2), there was no evidence of inflammatory changes in the material available for study. Negri bodies were most numerous in the single specimens of *E. fuscus pallidus* and *L. cinereus cinereus*. Both Negri bodies and inflammatory lesions were found in the brains of first-passage mice. Titers of virus and incubation periods in first and subsequent mouse-brain passages are shown in table 2.

Rabies antiserum was prepared in this laboratory with the National Institutes of Health-Pasteur strain PV-1 as an antigen. The serum was used in neutralization tests against the PV-1 virus, the rabies virus isolated in our 1954 bat studies, and the three strains isolated in this study. As a control, the serum was also used against a virus isolated by Dr. Harald Johnson from a bat and known not to be rabies. The serum neutralized all viruses to titer except the one obtained from Dr. Johnson. There was no evidence of reaction with the latter virus.

Discussion and Summary

Three of the 127 bats, comprising 7 species, collected in western Montana for the Rocky

A Survey of Chiropteran Rabies in Western Montana

By J. FREDERICK BELL, M.D., W. J. HADLOW, D.V.M., and WILLIAM L. JELLISON, Ph.D.

IN an earlier report from the Rocky Mountain Laboratory of the Public Health Service, Hamilton, Mont., we described the isolation of rabies virus from a bat caught in Ravalli County, Mont., in the late summer of 1954 (1). The lateness of the season limited collections in that year. However, in 1955 we made further attempts to isolate rabies virus from the bats obtained during field trips and by contributions from local residents.

Usually, bats were collected from roosts in attics with the gloved hand or were taken with forceps. Several infected bats were collected under circumstances which we will describe.

In the laboratory one lateral half of the brain of each bat was triturated in sufficient 1 percent albumin-saline diluent to make approximately a 5 percent suspension. A preliminary test for infection was done with each suspension by injecting each of 6 mice intracerebrally with 0.03 ml., and the remainder of the suspension was frozen. When the screen test was positive, the preserved suspension was centrifuged, and the supernate was titrated in mice. The other

half of the brain was fixed in Zenker's fluid for microscopic study.

Rabies From Three Species

One hundred twenty-one apparently normal bats were collected alive in routine collections in various parts of Ravalli County. The numbers of the various species examined are tabulated:

| | |
|---|----|
| <i>Myotis humanensis</i> | 14 |
| <i>Myotis lucifugus</i> | 47 |
| <i>Myotis humanensis</i> or <i>Myotis lucifugus</i> (juvenile)..... | 17 |
| <i>Myotis volans</i> | 3 |
| <i>Myotisotis</i> | 1 |
| <i>Myotis californicus</i> | 1 |
| <i>Eptesicus fuscus</i> | 37 |
| Unidentified..... | 1 |

These bats were brought to the laboratory and held in captivity a day or two until it was convenient to test them. None of their brain tissues produced rabies in mice.

Six other bats exhibiting aberrant behavior or found in unusual situations by people who knew of our 1954 findings were submitted for examination. Three of the six bats were rabid. The circumstances under which these three bats were collected are as follows:

A housewife in a small town about 6 miles from the laboratory brought the first infected bat, *Myotis californicus californicus*, to our attention. She said that her dog had bitten a sick bat, which was dead when a messenger arrived to collect it. The dog remained well during a 3-week period of observation.

The authors are, respectively, senior surgeon, pathologist, and parasitologist with the Rocky Mountain Laboratory, National Institute of Allergy and Infectious Diseases, Public Health Service, Hamilton, Mont. Dr. Charles O. Handley, Jr., of the Division of Mammals, United States National Museum, Washington, D. C., identified all the bats examined. The museum retained the infected specimens for reference purposes.

The State of the Nation's

public —
health —
services —

Abridged reports from the 55th Conference of the Surgeon General of the Public Health Service and the Chief of the Children's Bureau with the Association of State and Territorial Health Officers, the State Mental Health Authorities, and the State Hospital and Medical Facilities Survey and Construction Authorities, November 2-10, 1956, Washington, D. C.

New Highways To Health

**By Leroy E. Burney, M.D.
Surgeon General of the
Public Health Service**

Would that we health experts had the same precise knowledge in our field as the Nation's highway planners. For without it, we cannot plan new highways to health which would extend through all the States at the same rate of progress and standards of quality, and which would, by the very boldness and imaginativeness of design, capture public support.

I am not suggesting that we don't know what's going on in our own shops. Few public services have made as conscientious and unceasing an effort as public health agencies to collect and analyze reliable data pertinent to their statutory responsibilities.

But most of the facts that we have at our fingertips relate to the organizational structures, types of services, and ratios of professional personnel and facilities for a population of some 130 million in the social, economic, and physical environment of 20 years ago. Let's take a look ahead.

We need facts pertinent to a population of some 168 million today, 180 million in 1965, and 200 million by 1980. We need to see our organizations, services, personnel, and facilities

Continued on page 21

Mountain Laboratory of the Public Health Service, were found to be infected with rabies virus. The infected bats were *Myotis californicus californicus*, *Eptesicus fuscus pallidus*, and *Lasiurus cinereus cinereus*.

It is noteworthy that none of 121 bats collected while roosting were infected whereas 3 of 6 bats that exhibited abnormal behavior had rabies. The titers of virus in the brains of mice infected with the 3 strains were rather low and remained low even after several passages. Stamm and his associates (6) found the same to be true of one Florida bat strain. The three isolations from bats were the only isolations of rabies virus in Montana in 1955.

FDA Renews Hoxsey Warning

The Food and Drug Administration is intensifying its efforts to warn cancer patients and their families against the Hoxsey treatment for internal cancer. Help in disseminating the official United States Government warning is sought to offset increased promotion of the "treatment" launched following an adverse ruling against the Hoxsey clinic at Portage, Pa.

Information has been received that additional Hoxsey clinics are planned in other States. Hoxsey supporters are soliciting funds to "pay expenses" and "fight the medical trust."

On November 15, 1956, a Federal court jury at Pittsburgh sustained FDA charges that a half million pills seized at the Portage clinic were misbranded because they are of no value in the treatment of cancer. During the 6-week trial 80 witnesses, including some of the world's outstanding cancer experts, testified for the Government. Their evidence showed that persons claimed to have been cured by the Hoxsey medicines have since died of cancer; that others did not have cancer at all, while

still others were effectively treated by X-ray or surgery before taking the Hoxsey treatment. It was indicated that some users may have died of cancer because they relied on the Hoxsey treatment instead of seeking competent medical care in the early stages of the disease.

For more than 30 years Harry M. Hoxsey has made false claims for his liquid medicines and pills, and thousands of users have been deceived in spite of numerous local and State court actions.

Following the official public warning last April, FDA inspectors reported a very substantial decline in patients at the Portage, Pa., and Dallas, Tex., clinics. During the ensuing 7 months an estimated 3,000 to 6,000 persons were dissuaded from patronizing the clinics.

Copies of the FDA public warning may be obtained by writing to the Food and Drug Administration, Washington 25, D. C. A shorter public notice is also available for use in local newspapers, shopping news, farm, fraternal, and religious publications, or as a basis for radio or TV announcements.

for this larger and increasing population in entirely new settings: A rising standard of living, new patterns of urban and suburban life, larger families, more older people. Increasing automation, with consequent shift in the types of occupation and conditions of work. Emergence of entirely new industries. More cars, more trucks, more planes. Atomic power, much sooner than imagined. Increasing costs of hospital services, coupled with increasingly effective diagnostic and therapeutic techniques in the hands of the practicing physician. Increasing numbers of individuals and families seeking, but not finding, new types of health services in their communities.

We have some general concept of the gaps in our health programs. But a gap is not the sole measure of deficiency. We need to identify the causes of obsolescence and seek earnestly to remove them. It is not good business or good public health practice to hold on to obsolete procedures and activities.

We should address ourselves to this kind of appraisal, agonizing though it may be to some professional groups in public health practice. Our shortages of professional personnel are indeed vast. But, in our preoccupation with the estimated needs and no relief in sight, we have almost convinced ourselves that only more of the same will correct the deficiencies of our programs. On the contrary, we have at least two good alternatives: more effective use of professional public health personnel and the employment of other specialists and subprofessional groups.

Over the past 24 years, the American Public Health Association has sought earnestly to raise the standard of educational qualifications for the numerous specialty groups that make up the public health profession. In practice, however, too many of those who meet the qualifications are kept on outmoded activities which make no demands on their hard-won skills, have no use for their creativity, their burgeoning ideas. Too many are burdened with routine administrative tasks for which they have not been, nor should have been, trained.

Liberating Creative Powers

While pressing forward with every financial and educational resource at our disposal to in-

crease the supply of professional public health personnel, let us henceforth put a high priority on liberating the creative powers of our present and future staffs. Their ideas and imagination, tempered in the fire of meaningful experience, are what we need to design and build the new highways to health.

How then to remove the burden from overworked people who can't think, simply because there is no time to think? I have no ready answers to the question: no one individual can produce the best answers.

For what it's worth, however, try this on for size. If you had one or more specialists in public administration to share your burden of organizational and administrative planning and execution, or even enough administrative assistants to deal with the details of fiscal and budget matters, personnel administration, and so on, how much more time would you have to meditate: To meditate on the incalculable present and future problems in your area? To work and plan with your counterparts in State programs such as welfare, education, rehabilitation, housing, rural and industrial development? To consider with your fellow State health officers in nearby jurisdictions the urgent regional health problems of common concern?

We have made a little progress in accepting the idea of using less highly qualified nursing personnel as a means of conserving the skills of our scant supply of public health nurses. Clinic nurses and practical nurses are being employed in local health departments with increasing frequency. But, nationwide, we haven't employed nearly enough, or nearly enough clerks and clinic aides to allow public health nurses to serve the community as widely as they could if they did not also have to be record clerks, receptionists, and housekeepers.

Is there a possibility that all local health departments could benefit by the help of a volunteer group, something akin to the Gray Ladies of the American National Red Cross?

Perhaps some of the other health department programs, besides public health nursing, could use the services of volunteers. We are urging community surveys to get the facts upon which to base the needed modernizing of our programs. There are many jobs in community

Federal-State Cooperation: 1903-1956

The evolution of the Surgeon General's Conference with the State and Territorial health officers illustrates the durability of Federal-State cooperation in an ever-changing field. We are fortunate that Federal-State cooperation has been the usual order of business in public health for so long. This conference, established by law in 1902, antedates the provision of any regular mechanism for Federal-State cooperative planning and action in other matters of civil policy. It is still unique in that it is the only instance in which the entire body of State and Federal officials in a given field work together under law in an organized way.

Amendments to the Social Security Act Inter established an annual conference of the Chief of the Children's Bureau with the State and Territorial health officers. Then in 1916, the Public Health Service Act of 1914 was amended to require the Surgeon General to confer with State and Territorial hospital and mental health authorities. Since that time, we have had a joint conference of the Public Health Service and the Children's Bureau.

The broadening of these conferences reflects more than the broadening interest of the Federal Government in health. It reflects the broadening responsibility of the States and the notable strengthening of State and Territorial health programs. It also reflects many underlying and striking changes in health needs.

Let us compare, briefly, the first conference, in June 1903, with the 55th conference. The first conference met only one day. Twenty-two States and the District of Columbia were represented. In his annual report to Congress, Surgeon General Walter Wyman said of this meeting: "The delegates in turn gave synopses of the laws under which their respective boards (of health) operate, and a resolution was adopted favoring the formation of committees on special diseases and special consideration of such questions relating to the same as might be referred to them by the Surgeon General."

Those committees were on the following topics: scientific research and sanitation; prevention and spread of epidemic diseases; morbidity and mortality statistics; State legislation; and education. Subcommittees were appointed to report on cholera, yellow fever, plague, smallpox, tuberculosis, leprosy, and typhoid fever. It was agreed that resolutions of

future conferences were to be based on committee reports.

Fundamentally, that procedure has not changed. But what a difference today in composition and major topics of interest. The health officers here represent the 48 States, Alaska, the District of Columbia, Hawaii, Puerto Rico, the Virgin Islands, and Guam. Most are accompanied by program directors in one or more of the following fields: hospital and medical facilities, mental health services, maternal and child health and crippled children's services.

Through the Association of State and Territorial Health Officers, 7 permanent standing committees and 3 special committees have been in session and will present recommendations to the Service, the Children's Bureau, or to the association. It is noteworthy that none of the committees is concerned with one specific disease. Our concerns today are focused on Federal-State relationships, on broad categories of services and facilities needed for better health, and on people—mothers and children, American Indians, and migrant workers.

You have only to glance at the volume of the agenda to realize that this is a year-round working conference. Our Federal-State communications system is much more efficient. For this, we owe thanks to the association, its executive committee, the regional staffs of the Service, and the Children's Bureau.

There is another change. At that first conference and many thereafter, the initiative clearly came from the Public Health Service. Today, more often than otherwise, the initiative comes from increasingly vigorous and aggressive State and Territorial health departments.

I do not relinquish thereby one iota of the Public Health Service's responsibility for aggressive leadership. But we have only to glance at the international news to realize that exclusive leadership is the loneliest, the most sterile, and the least permanent. It is because our country has joint leadership in public health—Federal-State cooperative leadership—that all of us can undertake our individual and collective responsibilities with confidence and hope.

—Excerpts from the opening remarks of
SURGEON GENERAL LEROY E. BURNET.

forded most of us by our good will toward man and our intuition.

The community is our field. Here we must demonstrate the value, and the very reason for being, of public health and preventive medicine, or we fail. And the community is not so many square miles of structures, so many sewer lines and water pipes, so many birth and death certificates and case reports. The community is people of all ages, of all sorts and conditions, and they all behave not only as individuals but as groups, bound in many and widening circles by common beliefs, attitudes, and needs.

We often draw an analogy between the role of the personal physician and the local health officer. We say that as the former is responsible for diagnosing and treating the individual patient, using the services of specialists when they are needed, so the latter bears a like responsibility to the community. If this be so, I would say the local health officer needs a consultant in behavioral science perhaps even before he begins to diagnose, and certainly before he institutes any form of therapy requiring the acceptance, consent, and action of any sizable part of the community. If some of you think I go too far along this line, there is a growing experience and literature to bolster my contentions. Take a look, for instance, at "Health, Culture, and Community," edited by Benjamin David Paul. You will find these studies, some drawn from our own American society, illuminating and stimulating.

Medical and Related Research

That mention of studies reminds me that I have said nothing so far about medical and related research as a prerequisite to modernizing our highways to health. Perhaps this is because so much has already been said that some of us begin to think that all the basic and applied answers to our major health problems must be found before effective changes in services and programs can be made. We want, and must have, research and application going forward shoulder to shoulder.

Let me say that the Public Health Service will do everything in its power to promote and assist the development of research in, by, and with State and local health departments.

By and large, the findings of the past decade have found swifter, more widespread application in medical practice and hospital care than in public health programs. There is a special bridge that needs to be built to give us the needed shortcut. And that bridge is the kind of operational research that health departments are eminently suited to undertake. Actually, many of the questions I have been raising can be answered only by careful studies.

Also, our health departments must take a much more important part in epidemiological research than they have been taking. Some of you may recall Dr. Joseph Mountin's statement: "The health department is the only place a young physician can study healthy people along with the sick." The same could be said of the medical research scientist. The study of human biology and pathology in its natural setting, the human community, is indispensable. The principles of epidemiology have been developed and applied to parts of that essential study by public health scientists as their profession's unique contribution. Our major contemporary health problems present a challenge to epidemiology, no less than to experimental and clinical research. Our health departments should join with their scientific colleagues in taking up that challenge.

Besides the unquestioned additions such studies will make to public health knowledge and methodology, we shall realize untold benefits in removing one of the major causes of obsolescence in our health programs. And that is the isolation of many State and local health staffs from the stimulus of scientific inquiry and fruitful contacts with academic and research institutions. I see cooperative research, involving health departments with universities, or schools of public health, or medical schools, or the Public Health Service, as an aid to recruitment such as we have not had in years.

The few issues I have discussed by no means cover the gamut of problems we face together nor the victories we have shared. They have seemed to me especially important at this point in time, when the future strength and competence of our Federal, State, and local health departments seem especially vital to our Nation.

Someone has said that "ideas are the life of a people." The effective planning and develop-

surveys for specially trained and disciplined volunteers. They would never lack work to do in a local health department, I warrant.

In the same connection, can we use our personnel, facilities, and funds at the local level more efficiently by doing some of the essential jobs regionally and with more automation? Modern means of communication and our great new system of highways are leveling the road-blocks of time and distance. We should use these facilities to help break some of public health's traffic jams. I am thinking especially of local laboratory services and statistical programs. Perhaps we could have more specialists in local health services if we were willing to regionalize these activities.

Meantime, the Health Amendments Act of 1956, which became law (P. L. 911, 84th Cong.) on August 2, 1956, has made a good start toward increasing the supply of professional public health personnel, nurse educators, nursing supervisors and administrators, and practical nurses. By October 31, 32 schools of nursing and graduate schools of public health had applied for grants under title 1 of the act. The number of traineeships requested far exceeded our expectations, and even further the resources, \$1 million, available for this year. For example, we have been able to approve only 130 of 276 traineeships in public health nursing requested by the nursing schools, and only 47 of the 84 traineeships requested by the schools of public health. In addition, the Service has awarded 89 individual traineeships.

In the program for the advanced training of professional nurses under title 2, we have proceeded along the same lines. The 1957 appropriation for this program is \$2 million; grants are made to schools only. By October 31, grants had been awarded to all 56 eligible schools, covering traineeships for 553 students. More than 400 traineeships requested could not be awarded for lack of funds.

The training program for practical nurses is administered by the Office of Education of the Department of Health, Education, and Welfare. Two million dollars has been appropriated for traineeships, which will be awarded in the form of grants to the States. For every \$1 made available by a State in its expanded practical nurse training program, the Federal Gov-

ernment will grant \$2 to provide traineeships, up to a total Federal expenditure of \$2 million this year. A commissioned nurse officer of the Public Health Service has been detailed to the Office of Education as a consultant in the practical nurse training program. A citizens advisory committee is being assembled to help in the administration of the program, and nursing consultants are being employed to aid in expanding enrollments in practical nursing schools.

These new Federal programs to help augment the supply of health personnel by no means reduce, but possibly increase, the needs for inservice training at every level—national, State, and local. The simplest types of inservice training are those concerned with the use of new techniques and new equipment. The application of the cytologic test for preinvasive cervical cancer is a case in point. So also is the use of air pollution detectors and a host of other new techniques which could be widely applied if more subprofessional personnel were trained to do those parts of the procedure within their competence.

At professional levels, broad orientation in certain new problem areas must be provided on the job or in regional short courses for staff members who completed their academic training before the information now available had been developed. I have in mind such fields as radiological health, up-to-date civil defense and disaster relief, and regional development.

Understanding of Human Behavior

In all our tooling up to design new highways to health, we should recognize our public health profession's need for some orientation, some training in the behavioral sciences. The day will come soon when many State health departments will have a specialist or two from the fields of psychology and cultural anthropology on their permanent staffs or as frequently used consultants. The few that now have such specialists and we in the Federal agencies will learn to use their services more effectively. For it should be clear to all of us by now that the health programs of the future will lead nowhere if they are not based on a sounder understanding of human behavior than is af-

training centers where it appeared that need existed. The universities and the teaching centers historically have served as bases for training people. At the outset, we found these centers, as a whole, needed improvement, both financially and programwise. Accordingly, the institute gave high priority to grants for this purpose.

The grants program was initiated in 1947. In the years since, the institute has made grants to medical schools to improve or expand psychiatric instruction to the medical student. During fiscal 1956 alone, grants were awarded to 72 of the Nation's 84 medical schools. This aid means that 26,000 of the total 28,000 medical school students will receive more and better psychiatric instruction, to enable them to deal more effectively with the emotional problems of their patients.

Grants in another area have been directly responsible for the inauguration of mental health curriculums in 6 of the 10 schools of public health. Moreover, teaching centers for psychologists, psychiatric social workers, and psychiatric nurses have come in for their share of grants from the institute. Another technique sponsored by the institute to encourage well-rounded training is the series of regional conferences for professors of psychiatry in medical schools in the west and the south.

About 4,000 individuals have received stipend support for training during the 10 years the grants program has been operating. During fiscal 1957, 440 training grants, including 1,800 stipends, will have been made.

This, admittedly in brief, is the picture of support for mental health training at the national level. All of us, I think, can be justly proud of the progress and the accomplishments to date. At the same time, all of us know that the numbers already trained do not nearly approach the total need. The institute has never felt that it could or should singlehandedly take care of the vast training needs for the entire Nation.

The responsibility is a joint concern. It seems that the States recognized and acted on their training obligations a few years ago to a greater extent than they do today. In 1948, in the early days of the grants to State programs for mental health, the record shows that

the States used no less than 14 percent of available funds for preservice training of personnel. But in 1955, only 2 percent of State funds were spent for this purpose. In actual dollars, State expenditures dropped from \$840,000 in 1948 to \$360,000 in 1955.

One conclusion to be drawn from these figures is that the States' outlays for training in recent years are negligible amounts when compared with 1948 records. Less and less money is being spent by the States for training people in spite of the fact that the need to give services has skyrocketed. The demands for services everywhere grow greater, mental health centers are planned and funds for personnel are available, but the mental health workers are not to be found at any price.

Need for Trained Workers

I appreciate the constant and continuing pressures you face. But we must keep training in proper perspective. When many of the State programs were getting started, people were trained because they were a sheer necessity. Without the trained workers, programs could not develop beyond a certain point. There are limits to how far workers can be stretched to cope with community mental health needs. For the improved programs the public is demanding, more and not fewer workers must be trained.

We can begin to come to grips with the need for trained workers by looking at the training centers and the areas which more nearly approach their manpower needs. What is it about certain training centers that attracts residents and well-prepared faculty members? Location of the center is high on the list of desirable characteristics. The individual should have access to adequate and ample reference material. He has opportunities for professional growth through participation in research, for work and contact with influential teachers in many fields of learning. The element of prestige in such an environment cannot be overlooked. The trainee's or the faculty member's working conditions are much more satisfactory. He has smaller patient loads, with all that this implies for adequate supervision. Time off for clinical work and for supervision in special

ment of our health services is no less dependent on ideas. And at the present time of transition, no idea is too simple to be unworthy of a trial. We cannot build health highways by talking, but only by putting ideas to work. This means that top level health officials must be receptive to ideas, even to ideas that suggest the abandonment of obsolete procedures and activities, the development of new programs and methods of organization and staffing.

NOTE: The full text of Dr. Burney's address included a section on aging that appeared in the December 1956 issue of Public Health Reports, p. 1168.

Training Mental Health Personnel

By Robert H. Felix, M.D.
Director, National Institute
of Mental Health,
Public Health Service

The serious need for trained mental health manpower is one matter that necessarily occupies much of our time and energies. This area of concern was uppermost as long ago as 1946, when State and Territorial health officers and State mental health authorities met in joint session for the first time in the history of the Public Health Service. We have struggled with the problem in the ensuing 11 years, and today it is still with us in greater proportions than ever before, in spite of the thousands of people who have been trained, because mental health activities on all levels are increasing.

The requirements for more trained people are evident in all parts of the Nation. Some specific information on the situation in one section of the country with regard to one class of personnel will help pinpoint the problem. I am referring to the data on the resources and needs in the 16 southern States, provided by the survey conducted in 1954 by the Southern Regional Education Board. The survey findings resulted in the estimate that the south needs 4,260 psychiatrists for all purposes, or more than 5 times the number it has now. The

shortages of other workers are equally acute: 7 times as many clinical psychologists, 5 times as many psychiatric social workers, and upward of 5 times more psychiatric nurses than are available.

A closer look at the survey findings reveals that only 272 psychiatrists were expected to be trained in the entire south during the 3 years following the study. In other words, the south in 1957 will still be faced with a shortage of about 4,000 psychiatrists. At that rate of training, it would take many years to obtain the needed psychiatrists, and in the meantime the number required undoubtedly would increase considerably.

The comprehensive survey of the Southern Regional Education Board took into account the personnel required for public programs at all levels, as well as those for private practice and for training-center facilities. We have looked around us, and we know that, while the training centers and the urban areas have their problems with regard to shortages of personnel, they are relatively in a much better position than are other programs. By far the greatest number of staff vacancies exists in State programs, in the community mental health clinics, and in the mental hospitals. The teaching center, for example, may need only an additional man or two to round out its program. Many operating programs, on the other hand, may need one or more professional mental health personnel to initiate activities or to replace its part-time activities with full-time services.

Far too many mental hospitals are struggling along with grossly inadequate staffs. We estimate that the hospitals have only about one-half the number of psychiatrists they should have to provide adequate treatment for the patients under their care. The deficit of nurses, psychologists, and social workers is even greater.

Grants Program of Institute

The support and encouragement of training has been a vital phase of the National Institute of Mental Health's activities. Our approach has necessarily stressed support for the existing centers of learning. At the same time we have tried to stimulate the development of additional

The system of associated psychiatric faculties is employed to facilitate this integration of learning centers, hospitals, clinics, and other agencies for training. In many cases, the institution's staff helps out with didactic instruction in the training center's program.

The varied background which this kind of training provides is the kind of orientation State and community mental health personnel need. I wish I could report that all of our young people are receiving this kind of training, but we know all too well that they are not. Indeed, I am amazed and surprised at the vast differences in training one observes in one institution or another. Trainees in psychiatry, for instance, may be quite effective in working with psychotic patients but know little or nothing about working with schools and community agencies.

I am not, of course, opposed to highly specialized psychiatrists or other workers. We need this kind of personnel also. I am saying, however, that training is not equipping many people to do the community mental health work they have chosen. Their formal training does not give them the experience for the problems they inevitably meet. The omissions in instruction are understandable when we consider that some teachers are themselves handicapped in the same way. They, of course, pass their blind spots on to their students.

Both the trainee and the teacher, then, need a knowledge of the community's organizations and its institutions. I cannot help wondering how many psychiatrists have started careers in clinics, for example, only to become uncomfortable at finding themselves unprepared, and have turned to private practice instead. Integration of institution staffs and the training center faculties is one remedy for this situation, and each group will derive help from the other.

Regional Network

The States can derive tremendous benefits from such cooperation. I can think of one State hospital which until recently was a fairly typical mental institution, short of staff, training programs, and research projects. Now it has more applications for residencies than it has vacancies. The reason for this brightened pic-

ture is participation in a training network that embraces the State university, a good clinic, a Veterans Administration hospital, and other agencies.

Many of the States are equipped to develop fertile fields for training within their boundaries. All that is needed is a central plan and the establishment of the necessary cooperative relationships. One State has two medical schools, and one of these has a very good psychiatric unit. Each school is relatively near a mental hospital. Both hospitals, in turn, are good ones and one of them is new. Also, a good child psychiatric center offering residential treatment is located in the same city with one of the medical schools. This particular State could undoubtedly arrange for cooperation between its training centers and its institutions in the very near future.

I cannot tell you that the job will be a short or easy one, for the whole training problem is long range. Now is the time, however, for action on realistic training programs designed to meet our needs. I would strongly urge the establishment of a working group of this association, to consider specific plans for the development of cooperation between training centers and your operating institutions and agencies. The National Institute of Mental Health stands ready to provide all possible aid.

I envision the goal of your training activities as being the development of a central recruitment and employment source within the State. Communications between States and training centers by way of regional State groupings, such as the Southern Regional Education Board and the Western Interstate Commission for Higher Education, could speed the realization of such sources. Anyone within the State could turn to the central source for personnel needs, and the State would be prepared to refer to sources for trained workers.

We are not the only ones who are wrestling with the need for more mental health personnel. State legislators throughout the Nation are also searching for solutions. I have talked with many of them, and I know that they are looking to us for leadership.

The American Psychiatric Association, as well, is deeply concerned with our needs. At the fall meeting of APA's council, I pointed out

areas can usually be arranged. If he wishes, the individual may branch out into fields other than his own, and the total environment provides stimulating intellectual contacts.

Obviously, then, the answer to some of our manpower problems lies in bridging the gap between the training center and the State programs. Is it possible to initiate developments designed to create some of the same advantages the training centers have? You can do all in your power to influence the location of proposed new hospitals near universities. You can work to set up research units within your hospitals. Faculty arrangements and exchanges between universities and hospitals and mental health centers can be worked out. From time to time, opportunity can be given staff of these installations to take additional work at the university or under faculty supervision. Seminars can be arranged through the training centers and authorities from outside the State can be brought in periodically.

There is considerable advantage, both to the individual and to the program, for continuation of training on the job or on an intermittent basis after the period of formal preparation is completed. Professionals in the mental health field are usually trained in psychiatry, psychology, public health, social work, or nursing. Usually, these people come to the job as representatives and protagonists of their particular discipline, and with all of the biases and narrowness such training usually produces. What is needed in mental health work is not a collection of specialists brought together to practice their professions but rather a staff who bring a variety of skills which, taken together in proper proportions, will be much more likely to result in the best solutions. Unfortunately, this attitude is rarely developed in a training center, but the need for this point of view usually becomes apparent rather quickly once the worker begins to apply his training on the job. With the realization of this need, there is motivation for a broader and more useful type of training. When opportunity is provided to meet this need, one can look forward to a much better integrated and useful staff.

In addition to the advantages, inservice training has a byproduct which may be more valuable for the future than the original purpose of

providing better preparation for people already employed. The training centers are brought to realize wherein they are falling short in preparing their students, and with continued pressure applied by the students and the agencies which employ them, it is much more likely that the centers will provide the needed training either in the regular curriculum or in special courses.

It seems that these are activities in which States and communities can properly and profitably invest money and energy.

Community Health Work

How are we going to get people to take training, and also, how do we obtain the necessary qualified people to do the training? The motivations, of course, are not necessarily the same in all disciplines within the mental health field. Also involved are the clinics and hospitals and whether they are motivated to provide adequate and acceptable training, or, if unable to do this, to provide training in certain areas which can better be obtained there than elsewhere. We must recognize that the hospital which is far removed from the training center may not be able to obtain many new residents in psychiatry, for instance: but, while the institution may not be able to provide all a student's necessary training, it may well be ideal for providing experience and supervision in special segments.

Where an institution carries on an active program of research in special areas, it can often develop a rather wide reputation, and if this program is really excellent, there will be demand for opportunities to spend some time there. Some such special areas are aging, mental retardation, alcoholism, rehabilitation programs, programs with the schools, and closely integrated hospital and community programs.

This is what is actually happening in some places where State and community hospitals and extramural programs are integrated with training centers. There are numerous possibilities to obtain training in a variety of settings. Students, for example, may wish to obtain some supervised experience in the penal system or in another type of institution such as the juvenile court although they might balk at spending the entire training period there.

carry responsibility for children would have in a usable form the viewpoints, findings, and implications of studies of child rearing, child care, adult-child relationships, and of family and community provisions for children which appear to have a bearing on healthy personality growth and development.

Second, not only must we make more effective use of the research and clinical information we have, but we must broaden tremendously our knowledge about mental health, its cultural, personal, and environmental foundations, and its sources.

We need to know much more about the sources of emotional strength that help children withstand the inevitable destructive influences that make for mental and emotional disturbance. Greater understanding of these main-springs of mental health is a crucial part of the equipment of professional workers serving parents and children, and only research can supply it.

At the same time that we advance along the path toward the prevention and cure of mental illness, we need to test the knowledge we have and the knowledge we gain by evaluative research that will tell us to what extent the programs and services offered in these fields are effective.

More evaluative research must also be undertaken to give us a better picture of our successes and failures in maternity clinics, child health conferences, and school health services, in the use of the group process for helping parents, in the methods used by private physicians, in the care of children in hospitals, in institutions or foster family homes. With new and clarifying guidelines that could be derived from such studies, our work could be greatly improved.

Third, ways and means must be found to include in the teaching programs of schools of medicine, public health, nursing, social work, and law much more theoretical and practical instruction in child growth and development than is now included.

Recently, a prominent child psychiatrist stated that, for about 80 percent of emotional problems of childhood, care from psychiatrically trained personnel would not be needed. He believes that pediatricians and public health personnel could handle most of these problems

if they had adequate training in the development of children. In view of the continued overcrowding of child guidance clinics, it appears essential that nonpsychiatrically trained personnel learn to handle more effectively the more superficial problems.

What is needed to help bring this about is the introduction into schools of medicine, nursing, public health, social work, and other educational programs of an adequately supported teaching program covering the essentials of total child growth and development, and an understanding of interpersonal relations. Already some departments of pediatrics have begun to do this. Certain schools of public health nursing and schools of social work have also enriched their curriculums in this way. I regard such a training program as a vital undertaking and one that should have the support of all concerned with the business of child rearing.

I have dwelt somewhat at length on the need for this training program because of its long-range implication for the health of children and youth and because of its significance in any and every effort to advance toward a real base for peace.

At this point I would like to refer briefly to a few items of interest that have importance for the future.

Radiological Health

A few months ago, a document of great significance to child development and to the population as a whole was published. I refer to the report of the National Academy of Sciences-National Research Council on "The Biological Effects of Atomic Radiation." The most striking aspect of this report is the relative importance for our population of cumulative exposure to X-ray and fluoroscopy. As you know, the human embryo, the fetus, infants, and children are especially sensitive to X-ray radiation. The results of radiation may range from genetic mutations in succeeding generations when the gonads are exposed, to embryonic damage when a pregnant woman receives excessive dosage on the pelvic organs, to damage to the blood-forming organs with resulting leukemia when radiation to the whole body is excessive.

the obligation of organized psychiatry and teachers to provide the necessary stimulation and experience for public mental health workers.

Our States and the psychiatric facilities are dynamic entities, ever on the move to accomplish their objectives. Foremost among their more immediate goals should be the development of cooperative relationships for more realistic and appropriate training. The goal of fertile training soil for our mental health personnel-to-be is surely worthy of our best efforts.

Perspectives In Child Health

By Martha M. Eliot, M.D., Sc.D.
Former Chief of the
Children's Bureau

I am glad to be with you once more and to report to you on some activities of the Children's Bureau during the last year.

No one here has to be told what a long way we have yet to go before we attain that level of physical, mental, and social maturity that enables people to solve international problems *without resort to armed conflict*. Many of you would agree with me that we have made some progress, even though small, in recent years toward this goal. But may I say to you, who are the leaders in the field of health, that the contribution to that progress which you can make in the years ahead is tremendous.

If you ask me what you should do, my answer would be, look sharply and long at what each of you and your colleagues are doing to start a whole new generation of children on the road to healthy development, not just in body but in total personality. This calls for a generation of parents who understand more fully than most do now the meaning of their relationships with each other and with their children. It means a generation of parents who accept as fact what Dr. Brock Chisholm some years ago called "the most important business in the world, the one that outweighs all other values

in the world," the business of rearing children.

Basically, it means that all professional persons coming in contact with parents will themselves require an understanding of what is meant by healthy personality development in a child and how it is brought about. Often, an early contact, even before the birth of a baby, may be made by a child welfare worker, a teacher, a minister, a lawyer, a nutritionist, or by other health and welfare workers. But the role of child health workers—physicians, nurses, and many others—is of primary importance, for it is usually they who, year after year, will have the opportunity to make the earliest contact with young parents who are new to this business of child rearing.

Support for Professional Workers

It is an important matter, then, that we should be constantly seeking ways to help professional workers understand the facts and the meaning of child growth and development and how each child is affected by the family environment into which he is born, by the biases and discriminations of the community in which he lives, by his physical and mental handicaps, and by many other factors.

If professional workers are to proceed in their activities with confidence that what they are doing and how they are doing it is based on up-to-date knowledge and experience, several moves are needed.

First, we must put the research information and clinical findings we have to better use. One of the most productive things we could do to promote healthy personality development and to prevent mental ill health would be to provide, to a variety of people, a continuous flow of information based on an evaluation and interpretation of research by workers well grounded in mental health concepts.

This kind of knowledge would be of value to professional workers, including those in operating programs, and the faculties of schools of medicine, public health, nursing, and social work. Such professional workers may often find it impossible to keep up with the great stream of knowledge flowing from research relating to children.

Parents, citizens groups, and others who

years may rise by about 21 percent to a total of more than 67 million in 1965. This increase in child population will necessitate a continued expansion of the maternal and child health and crippled children's programs even if the only objective is the maintenance of the present rate of services.

The cost of providing health services continues to rise. The salaries of medical personnel in State health departments have increased 63 percent between 1947 and 1953. Salaries of public health nurses increased 74 percent. Hospital costs rose from an average of \$16.89 per patient-day in 1950 to \$22.78 in 1954, an increase of 35 percent. These are basic economic challenges which we must meet if our programs are to serve mothers and children even at present levels.

While infant mortality in the country as a whole has been reduced to a new record low of 27 per 1,000 infants born alive, infant losses in the perinatal period continue at a relatively high level. In 1954, for the United States as a whole, about 36 infants per 1,000 reported pregnancies were born dead or died in the neonatal period.

On the incidence and prevalence of maternal morbidity, we have few epidemiological facts to guide us. We do know, however, that more than 300,000 mothers a year in the United States are unable to carry their infants to term. This impairment in maternal health is associated with very high perinatal mortality in the infant.

We are following with much interest the reports on the effectiveness of the hormone Releasin in halting premature labor. If early results are confirmed, health departments will have a new agent to apply in the programs to reduce premature births and fetal and neonatal deaths.

Shift in Pediatric Work

With the American College of Obstetrics and Gynecology and the American Academy of Pediatrics, the Children's Bureau is sponsoring a project to develop more effective analysis of maternity and newborn infant hospital records with a view toward improving the care of mother and child in hospitals. This project is

planned as a 3-year study to be conducted in all hospitals in a cooperating community. The project will develop and demonstrate ways and means by which hospital staff can obtain maternity and newborn infant statistics useful not only to the individual hospital but also to the community as a whole in maintaining a high level of maternity and neonatal care. When the method is tested, we look forward to its use by many different kinds of hospitals, large and small, teaching and nonteaching, where the births in the United States take place.

Much progress has been made by the States in the past 20 years in the development of the crippled children's program with a major emphasis on orthopedies. Now, with the availability of specific therapeutic agents for many acute diseases, we are seeing a shift in emphasis in pediatric work. Throughout the country there is an increased interest among pediatricians in the care of children with chronic disease and handicapping conditions.

The long-range problem that I see ahead of us in the crippled children's program is to find the way to develop in each State adequate resources for the care of children who are handicapped and require long-term medical supervision and rehabilitative services. The number of children with handicaps other than orthopedic in nature are estimated to be nearly 10 times the number of orthopedically handicapped children. Yet they represent less than one-half of the children now receiving care under the crippled children's program. In developing clinics and other services for children with epilepsy, cleft palate, congenital heart disease, hearing impairment, limb amputations, and so forth, you have unusual opportunities for putting to work the knowledge that research is providing. Research makes it possible to treat or ameliorate much of childhood crippling, to rehabilitate children, and to prevent the progression of disability.

There are of course many more phases of your programs for children on which I could comment. I would like to make just one more point which has to do with the role State health departments play when the responsibility for health services or medical care for special groups of people rests in other State depart-

The report is specific with respect to the maximum cumulative exposure to the gonads that is safe according to present knowledge. It recommends the adoption of a national standard of maximum exposure to radiation that is consistent with safety. The report also emphasizes the importance of reexamining current practices in the use of X-ray or fluoroscopy in providing medical services. Some of these appear to expose infants and children and prospective parents more than is necessary or wise.

Partly as a result of your interest and that of the Association of Maternal and Child Health and Crippled Children's Directors, and because of a recommendation of the United States National Committee on Vital and Health Statistics, the Children's Bureau is establishing a National Committee to Reduce Hazards to Inheritance and Child Development. Its members will represent a number of scientific disciplines and relevant programs in the maternal and child health field. This committee will give national leadership to planning for research and other activities designed to reduce reproductive wastage and safeguard normal fetal development.

A related committee on radiological hazards is being planned concurrently with the overall committee. It will develop proposals to promote good radiological techniques, particularly as applied to children and pregnant women. The work of both of these committees will be reported as they get under way.

Child Health Programs

The Children's Bureau has welcomed the passage of the National Health Survey Act and looks forward to working closely with the Public Health Service in order to obtain the best information possible about the state of health of our child population. We know of your interest in the problem of congenital malformations and in children who have other types of crippling or handicapping conditions. We are looking forward to joint special studies to give us better information on the numbers and needs of these children than we have been able to obtain for many years.

The interest State health departments are showing in planning programs for mentally

retarded children portends a rapid and widespread development in this much neglected field. Congress, when it increased the maternal and child health grants from \$12 million to \$16 million, earmarked \$1 million for special projects for mentally retarded children and requested that an additional \$1 million be spent for this purpose. More than half the States are reported to be working on plans for programs for these children. Programs are already in operation in Arkansas, California, the District of Columbia, Hawaii, Idaho, and Washington; other requests are in the process of being approved. They are receiving fine support from parents and teachers as well as from the medical profession.

The rapidity with which the State crippled children's agencies expanded their programs last year when the grants were increased from \$11 million to \$15 million not only shows the need for services for children with chronic disease and handicapping conditions but testifies to your satisfactory administration of these programs. Otherwise such a rapid expansion would not have been possible.

A brief tabulation shows how these increased funds helped the crippled children's programs to grow last year. Thirty-nine States reported the increased funds were helping them to provide medical and hospital care for more children, and 19 States reported using the funds to help meet rising costs. The development of new and expanded programs, 20 of which were started in 16 States, includes the following:

| | States |
|-------------------------------|--------|
| Cleft palate..... | 9 |
| Congenital heart disease..... | 5 |
| Rheumatic fever..... | 8 |
| Hearing impairment..... | 15 |
| Epilepsy..... | 5 |
| Arm amputations..... | 2 |

The increasing child population and the mounting costs of these programs are in themselves basic problems. In 1955 the number of live births exceeded 4 million, a rate of 24.9 per 1,000 population and close to the highest in 30 years. The Nation's total child population under 18 years of age increased from 47 million in 1950 to 56 million in 1955, an 18 percent rise. The Bureau of the Census expects that between 1955 and 1965 the number of children under 18

The large deficit in mortality from diseases of the cardiovascular-renal system and from diabetes mellitus among Navajo Indians is too great to be accounted for by certain types of errors in death certification. Further epidemiological studies are required to explain why this tribe enjoys a more favorable experience with these diseases than white and other nonwhite Americans.

Cardiovascular-Renal and Diabetes Deaths Among the Navajos

By ROBERT LINCOLN SMITH, M.D., M.P.H.

IN A PREVIOUS paper Salsbury, Gilliam, and I showed that deaths certified as caused by cancer and by diseases of the circulatory and central nervous systems were substantially fewer among the Navajo Indians than would have been expected had observed white or non-white death rates prevailed (1). However, we pointed out that the apparent deficit of cancer alone could not be regarded as established beyond all reasonable doubt because of the large number of deaths in older Navajos for whom the cause of death was uncertain. Either the deceased had not been attended by the physician signing the death certificate or the cause of death had been assigned to senility. Nevertheless, the study clearly showed that the deficit in cancer and in cardiovascular-renal diseases,

taken all together, was too great to be accounted for by faulty death certification alone.

Other authors have also called attention to apparent deficits in these diseases among the Navajo Indians. Dealing with death certificate data, Hadley has noted that diseases of the heart, cancer, and vascular lesions affecting the central nervous system were not among the 6 leading causes of death for Navajos in 1950 (2).

Salsbury has observed that a diagnosis of some form of heart disease was made on only 0.4 percent of 4,826 admissions (mostly of Navajos) to the Sage Memorial Hospital at Ganado, Ariz., during the years 1931-35 (3).

Gilbert has reported that no clinically proved case of coronary thrombosis was found among 10,276 Navajos admitted to the Navajo Medical Center for the years from 1949 to 1952 (4).

In addition, Joslin (5, 6), Salsbury (7), and Cohen (8) have remarked on the infrequent recognition of diabetes among Navajo Indians.

Because of these observations, I have extended the analyses of the previous study on the Navajos (1) and have compared expected mortality with recorded mortality for the various specific causes that make up the broad cardiovascular-renal group of diseases. Since the data comprising this study approximate all of

Dr. Smith is an epidemiologist with the Biometry and Epidemiology Branch, National Cancer Institute, Public Health Service, Bethesda, Md. Formerly he was chief, bureau of tuberculosis control, Insular Department of Health, San Juan, P. R. (1948 to 1951), and medical consultant in chronic diseases, Public Health Service Region 3 and the Division of Chronic Disease and Tuberculosis, Public Health Service (1951 to 1954).

ments or agencies under either Federal or State laws or regulations.

As I see it, your minimum role is to make sure that preventive health services are included in all such programs and that the highest possible standards of care for the sick or disabled are set and adhered to. I am thinking of the new program of medical care for the dependents of men in the armed forces, especially the children among these dependents. I am thinking

of what you can do to work with the State departments of public welfare in raising standards of medical care provided for the aged and for dependent children under the new amendments to the Social Security Act that will become effective next July.

The benefits for our children to be derived from all of the programs I have mentioned represent a real investment in the future of our country, indeed, in the future of the world.

Dr. Eliot Leaves Children's Bureau

Dr. Martha M. Eliot has resigned as chief of the Children's Bureau, the office she held the last 5 of her 30 years of Government service. She returns to her native Massachusetts to head

the maternal and child health department of the Harvard School of Public Health.

In accepting Dr. Eliot's resignation, President Eisenhower noted her invaluable contributions to the "cause of better health and welfare of children, not only in our own Nation but around the world." In his letter he said, "I share with Secretary Folsom the hope that your new activities will be richly rewarding and that we may count upon your advice and help in the years to come."

Dr. Eliot was the first and only woman to be elected president of the American Public Health Association. For administrative achievement in organizing and operating a Government program that served a million and a half GI wives and infants in the Second

World War, Dr. Eliot was given the Lasker Award.

From 1919 to 1951, Dr. Eliot was Assistant Director-General of the World Health Organization. She was chairman of its Expert Committee on Maternal and Child Health in 1949, having served in 1948 as a member of the United States delegation to the First World Health Assembly in Geneva.

A graduate of Radcliffe with her doctorate from Johns Hopkins, Dr. Eliot began her long and distinguished career in maternal and child health services at the Peter Bent Brigham Hospital, Boston. She joined the Yale University Medical School in 1921 as instructor in the pediatric department from which she came to Washington as director of the Division of Maternal and Child Health in the Children's Bureau. There she directed one of the Bureau's first research programs, the prevention and control of rickets in children.

She served on the Board of Editors of *Public Health Reports* from its reorganization as a monthly periodical in 1952 until 1956.

The large deficit in mortality from diseases of the cardiovascular-renal system and from diabetes mellitus among Navajo Indians is too great to be accounted for by certain types of errors in death certification. Further epidemiological studies are required to explain why this tribe enjoys a more favorable experience with these diseases than white and other nonwhite Americans.

Cardiovascular-Renal and Diabetes Deaths Among the Navajos

By ROBERT LINCOLN SMITH, M.D., M.P.H.

IN A PREVIOUS paper Salsbury, Gilliam, and I showed that deaths certified as caused by cancer and by diseases of the circulatory and central nervous systems were substantially fewer among the Navajo Indians than would have been expected had observed white or non-white death rates prevailed (1). However, we pointed out that the apparent deficit of cancer alone could not be regarded as established beyond all reasonable doubt because of the large number of deaths in older Navajos for whom the cause of death was uncertain. Either the deceased had not been attended by the physician signing the death certificate or the cause of death had been assigned to senility. Nevertheless, the study clearly showed that the deficit in cancer and in cardiovascular-renal diseases,

taken all together, was too great to be accounted for by faulty death certification alone.

Other authors have also called attention to apparent deficits in these diseases among the Navajo Indians. Dealing with death certificate data, Hadley has noted that diseases of the heart, cancer, and vascular lesions affecting the central nervous system were not among the 6 leading causes of death for Navajos in 1950 (2).

Salsbury has observed that a diagnosis of some form of heart disease was made on only 0.4 percent of 4,826 admissions (mostly of Navajos) to the Sage Memorial Hospital at Ganado, Ariz., during the years 1931-35 (3).

Gilbert has reported that no clinically proved case of coronary thrombosis was found among 10,276 Navajos admitted to the Navajo Medical Center for the years from 1949 to 1952 (4).

In addition, Joslin (5, 6), Salsbury (7), and Cohen (8) have remarked on the infrequent recognition of diabetes among Navajo Indians.

Because of these observations, I have extended the analyses of the previous study on the Navajos (1) and have compared expected mortality with recorded mortality for the various specific causes that make up the broad cardiovascular-renal group of diseases. Since the data comprising this study approximate all of

Dr. Smith is an epidemiologist with the Biometry and Epidemiology Branch, National Cancer Institute, Public Health Service, Bethesda, Md. Formerly he was chief, bureau of tuberculosis control, Insular Department of Health, San Juan, P. R. (1948 to 1951), and medical consultant in chronic diseases, Public Health Service Region 3 and the Division of Chronic Disease and Tuberculosis, Public Health Service (1951 to 1954).

the deaths occurring in a whole and fairly well defined population group, the results provide a better idea of forces of mortality among the Navajos than could be obtained from analyses of admissions to, or deaths in, any one hospital serving the tribe.

Method of Study and Results

The first article described how the Navajo deaths recorded by the Navajo Indian Agency were tabulated for the 5-year period 1948-52 (1). Because we were uncertain about the exact population base from which death certificate data were available, we estimated the Navajo population on the basis of the published 1950 census enumeration (61,371) of Indians resid-

ing in the area served by the Navajo Agency and on the basis of the total number (70,567) of Navajos estimated by the Navajo Agency for the same year, distributing the population by sex and age as in the census enumeration. These population estimates yielded a minimum and a maximum number of expected deaths, computed by multiplying the 1950 age-specific, sex-specific, and cause-specific death rates for the entire white United States population by the corresponding estimate in each of the two Navajo population groups. The results summed for all age groups and multiplied by 5 comprise the number of deaths from each cause that might be expected to occur among the Navajo Tribe in the 5 years centering around 1950 if all Navajos had been subjected

Figure 1. Recorded deaths among Navajo Indians, 1948-52, which were attributed to cardiovascular-renal diseases and diabetes mellitus, and deaths expected on the basis of 1950 age-specific, sex-specific, and cause-specific death rates for the white and nonwhite populations of the United States.

Table 1. Deaths among the Navajos attributed to cardiovascular-renal diseases and to diabetes mellitus during the 5-year period 1948-52 and deaths expected on the basis of age- and sex-specific rates observed in 1950 among the white and nonwhite United States populations

⁸ In 3 cases death certificate signed by physician not in attendance.

to the same age-specific and sex-specific rates prevailing in the population of the United States as a whole.

The results of these computations are shown in figure 1 and table 1. Numbers in parentheses refer to diseases listed in the International Statistical Classification of Diseases, Injuries, and Causes of Death, sixth revision.

Only 105 male deaths during the 5-year period were charged to the major cardiovascular-renal diseases although from 531 to 692 deaths would have been expected on the basis of rates prevailing among the white and non-white United States populations (table 1). Deaths recorded from these causes were, therefore, only 15 to 20 percent of the deaths expected. Similar results are noted among women. Seventy-three deaths were recorded as compared with an expectation of 321 and 513 deaths. The standardized mortality ratios thus computed for women vary between 13 and 23.

Further examination of table 1 shows that this very large total deficit is contributed to by all of the individual causes of death except rheumatic fever. Rheumatic fever, however, accounted for only a small number and proportion of deaths. Five deaths were recorded for men and three for women. Note also that the differences between recorded and expected deaths are not great for chronic rheumatic heart disease, especially among Navajo women. When comparisons are made on the basis of rates prevailing among the white population, little difference is noted between expected and observed deaths for chronic and unspecified nephritis and other renal sclerosis (592-594), for hypertension with arteriolar nephrosclerosis without mention of heart (446), and for the category that includes acute and subacute endocarditis, acute myocarditis, acute pericarditis, and functional and other unspecified heart diseases (430-434). For these same diseases, however, substantial differences are noted in comparison with nonwhite experience.

Among the causes of death tabulated, the greatest deficit is observed for coronary disease (420.1), for which the mortality recorded is only 6 to 13 percent of that expected in men and only 7 to 9 percent of that expected in women. This deficit is equally as outstanding in the age

group 45 to 64 as it is in the group 65 years of age and older.

Diabetes mellitus (260) was the assigned cause of death for 3 men and 3 women, but the number of expected deaths varied from 12 to 13 for men and from 14 to 21 for women.

Discussion and Conclusion

In the foregoing I have shown that deaths attributed to cardiovascular-renal diseases among the Navajo Tribe are substantially less than would be expected had United States white or nonwhite death rates prevailed. With the exception of rheumatic fever, all of the major causes of death that were considered have contributed to this deficit. In evaluating the deficit, however, consideration must be taken of three facts to which the first study called attention (1).

The first is that deaths other than violent deaths among Navajos in the ages of highest cancer risk (45 years of age and older) which were unattended by a physician or which were assigned to senility and to other ill-defined

Table 2. Deaths attributed to cardiovascular-renal diseases,¹ difference between recorded and expected deaths

| Total..... | 370 | 358 |

causes were more than enough to account numerically for the recorded deficit of cancer. When this point is examined for cardiovascular-renal diseases, however, the deficit is too large to be accounted for in this way. Because of the greater uncertainty of correct diagnosis in the very old, we compared the deficit of mortality in the cardiovascular-renal diseases with the number of unreliably certified deaths among Navajos in the age groups 45 to 64 and 65 and older. The deficit in recorded mortality attributed to cardiovascular-renal diseases is shown in table 2, and the deaths assigned to senility or ill-defined causes and unattended deaths are shown in table 3.

Comparison of tables 2 and 3 clearly shows a much larger deficit of recorded cardiovascular-renal diseases in Navajos 65 years of age and older than could be accounted for even if all of the unreliably certified deaths were due to these causes. This is also true for Navajos 45 to 64 years of age, though to a lesser extent. For deaths occurring among members of the tribe under 45 years of age, the calculated deficit of cardiovascular-renal diseases for both men and women is much less than the unreliably certified deaths. There are, in fact, a few more deaths recorded from these causes than would be expected on the basis of the minimum estimate. However, it is reasonable to assume that most of the unreliably certified deaths in Navajos under 45 are properly assignable to causes other than cardiovascular-renal, especially since 200 of the 244 deaths in males and 209 of the 269 deaths in females occurred in individuals under 25 years of age.

Second, there was a question whether some of the excess Navajo mortality certified as caused by respiratory and digestive diseases might ac-

tuallly be due to cancer or cardiovascular-renal diseases. That this is unlikely is indicated by the fact that the excess mortality in these diseases is almost entirely limited to Navajo children less than 5 years old. This is also true, though to a lesser degree, for the excess mortality attributed to respiratory tuberculosis. Excess mortality for respiratory tuberculosis occurred principally in Navajos under 45 years of age. For those 45 years and over mortality from respiratory tuberculosis was only moderate.

A third consideration is the fact that age-specific death rates for all causes in older ages are lower among the Navajo Indians than among all Indians. The difference between these rates becomes progressively greater with age as is seen in figure 2. While this fact is suggestive of under-reporting of Navajo deaths in the older age groups, it is also consistent with the idea that the Navajo Tribe is subject to different forces of mortality from those operating for Indians as a whole. In any event, under-reporting must be considered as a potential factor contributing to the observed deficit in mortality attributed to cardiovascular-renal disease.

To test the possible effect of under-reporting, deaths for all causes recorded among the Navajos were compared with deaths expected had the tribe experienced the overall mortality of all American Indians. Though the results of these calculations are not illustrated, they did show fewer deaths from all causes among

Figure 2. Average annual age-specific and sex-specific death rates for all causes among all American Indians, 1949-52, and among the Navajo Indians, 1948-52.

older Navajo Indians, such as might have been anticipated from the rates shown in figure 2. It seems highly unlikely that all postulated under-recording of deaths could be attributed to cardiovascular-renal diseases alone. Even if it were, however, under-recording at its maximum was hardly sufficient to account for the deficit of cardiovascular-renal mortality shown in table 2. The evidence therefore favors the view that the Navajo Tribe experienced a real deficit of cardiovascular-renal disease. The true magnitude of this deficit cannot be assessed accurately from these data.

Analysis of mortality recorded among Navajo Indians supports the view that cardiovascular-renal diseases are less commonly encountered among this tribe of American Indians than in the general white and nonwhite populations of the United States.

Examinations Open for Scientists

Scientists in a number of medically related fields may now take examinations for civil service employment with the Public Health Service's Communicable Disease Center at headquarters in Atlanta or at center activities throughout the country.

Examinations are offered for medical microbiologists (bacteriologist, immunoserologist, mycologist, parasitologist, and virologist), public health biologist, chemist, and medical entomologist. Starting salaries range from \$5,440 to \$11,610. Ratings will be based only on experience and training. No written test is required.

The Communicable Disease Center plans, coordinates, and provides assistance to State and local health agencies in the control of communicable diseases.

Application forms and additional information can be obtained from any post office except in civil service regional headquarters cities, from the Civil Service Commission, Washington 25, D. C., or the Executive Secretary, Board of Civil Service Examiners, Communicable Disease Center, Atlanta, Ga.

Geographic Variation in Leukemia Mortality in the United States

By BRIAN MacMAHON, M.D.

DIFFERENCES BETWEEN countries in the recorded death rate from leukemia are considerable. Notable differences are evident even when countries with reasonably complete death registration are compared. For example, the United States, Denmark, and Sweden experience death rates from leukemia $1\frac{1}{2}$ times as high as those of Canada, Great Britain, and France, which again have much higher rates than Ireland, Italy, or Finland (1).

Geographic variation within countries has also been noted. Hewitt (2), examining death registration data for England and Wales, noted a fairly regular gradient from a relatively low level in the north to a level about half as high again in the south. Material from the Danish Cancer Registry (3) showed highest rates in the capital and lowest in the rural areas. Otherwise, there were no definite topographical differences in Denmark. Higher rates for the urban compared with the rural population have been noted also in the United States (4). Death registration data for leukemia in the United States have been examined on a number of occasions (5-8), but no study of geographic variation between regions or States within the United States has been reported.

The National Office of Vital Statistics of the

Public Health Service has published annually data on deaths from leukemia in the United States, classified according to State of residence, sex, race, and age, since 1949 (9). Prior to 1949 the reports did not include a breakdown by age for deaths from this cause in the individual States. The present study is based in the main, therefore, on data for the 5 years 1949-53. Attention is confined to the white population. Age-standardized death rates are shown in table 1 for the male, female, and total populations of each State and each division. The standard population used was the total white population of the United States in 1950; nine age groups were used in the standardizations.

In addition to the standardized rates, comparative mortality indexes for the individual States are given in table 1. These indexes express the observed number of deaths in each area as a percentage of the number of deaths expected in the area on the basis of (a) the age and sex distribution of the population of the area, and (b) the age-specific and sex-specific death rates from leukemia observed in the total United States white population.

Differences Between Divisions

The nine divisions into which the States are grouped are those used by the Bureau of the Census. Differences between them in leukemia death rate were not great. The highest division, Pacific, with a mean annual death rate of 69.9 per million, was 20 percent higher than the lowest, East South Central, with a rate of 58.4.

Dr. MacMahon is associate professor in the department of environmental medicine and community health, State University of New York, College of Medicine at New York City. Hamilton A. Harriss, of the same department, assisted in the computations for the study.

¹ Values are not calculated for States with less than 500,000 white population in 1950.

All three southern divisions (East South Central, West South Central, and South Atlantic) had rates lower than any other area. By contrast, rates were highest in the west. The Pacific, Mountain, and West North Central divisions ranked first, second, and fourth in order of leukemia death rates.

Since Meadors (4) found the leukemia death rate approximately $1\frac{1}{2}$ times higher in the urban than in the rural population of the United States, some relationship between leukemia death rate and degree of urbanization of the area might be expected. The lower leukemia death rate in the three southern divisions is consistent with this expectation. However, among the other six divisions, the death rates showed little relationship to the pattern of urbanization. The two divisions with the highest leukemia rates, Pacific and West North Central, were third and seventh in a listing according to urbanization. The two most urban divisions, Middle Atlantic and New England, ranked third and sixth according to leukemia death rates. Meadors' finding was based on a direct comparison of the urban and rural populations and is therefore in no way invalidated by the finding of high leukemia rates in areas with low urbanization, or vice versa. It seems likely, however, that the urban-rural difference in leukemia death rates was operating during the period of the present study to reduce some of the geographic differences between divisions.

Adjustment of the divisional death rates is possible on the basis of the known percentage of the population of the division classified as urban, and the assumption that the rates for the urban population were $1\frac{1}{2}$ times higher than those for the rural population in each division. This assumption was made on the basis of Meadors' findings for the whole United States. After adjustment on this basis, divisional death rates were West North Central 72.7, Pacific 66.8, Mountain 66.3, East South Central 64.9, West South Central 64.3, East North Central 63.1, South Atlantic 62.6, Middle Atlantic 61.9, and New England 59.1. The adjustment has raised the rates for the southern divisions relative to divisions in the northeast, suggesting that the originally low rates in the south may result from

the lower percentage of urban population there. However, the adjustment has accentuated the difference between the west and the northeast. The three western divisions now rank first, second, and third in order of leukemia death rates.

Differences Between States

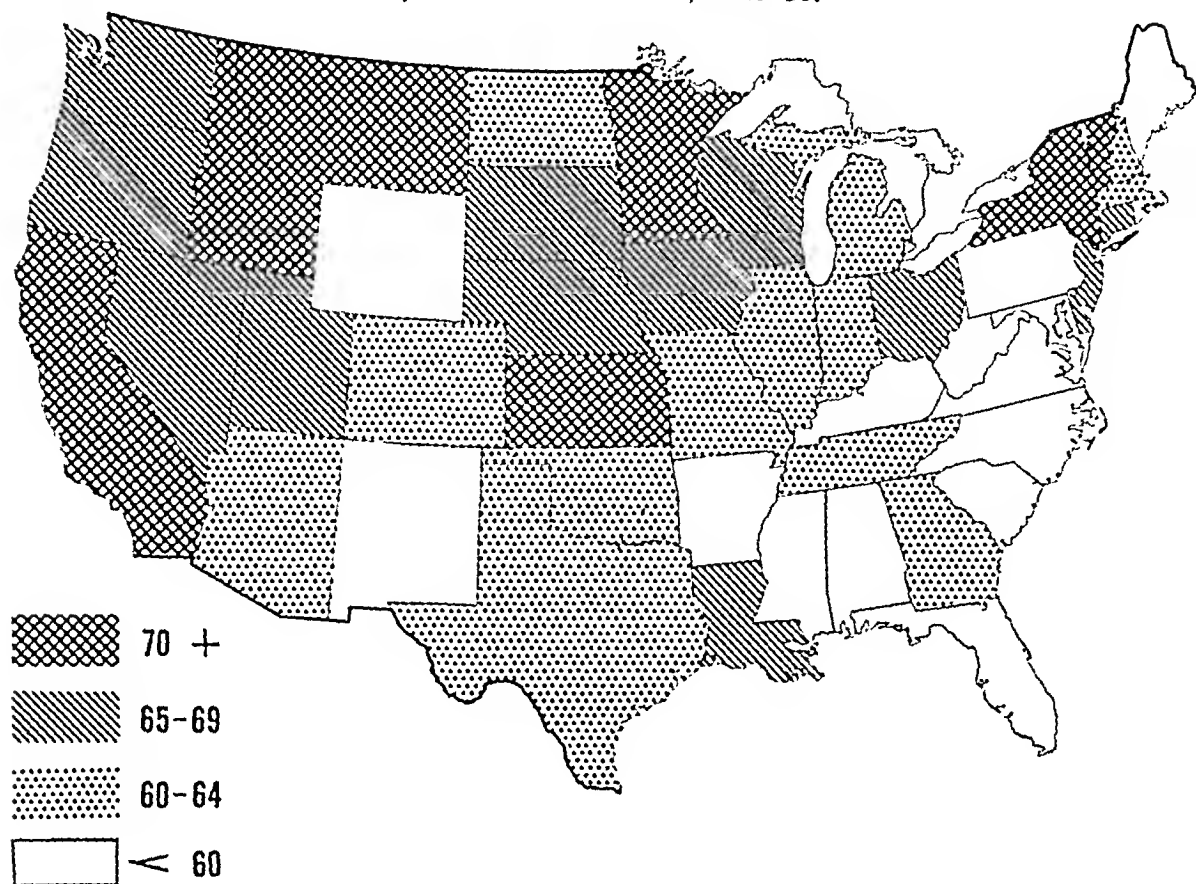

The individual States showed greater variation in leukemia death rates than the divisions (table 1, fig. 1). States with the highest rates in 1949-53 were Minnesota (79.2), Vermont (73.8), Montana (73.2), Idaho (72.5), California (71.0), New York (70.6), and Kansas (70.6). Lowest rates were in Maine (50.0), Wyoming (50.3), Rhode Island (50.7), and New Mexico (52.9).

Greatest variation in leukemia death rates was between States constituting the New England and Mountain divisions. New England included the second highest State (Vermont) as well as the 46th and 48th (Rhode Island and Maine). In the Mountain division there was disparity between the four northwestern States with the rates of 73.2, 72.5, 65.3, and 66.1, and the four southeastern States with rates of 63.4, 61.0, 52.9, and 50.3. The three Middle Atlantic States showed less variation, from 70.6 in New York to 59.8 in Pennsylvania.

On the other hand, the States constituting the three southern divisions showed fair uniformity in their low individual rates. Of the 17 States (including the District of Columbia) in these divisions, only the District of Columbia, Delaware, and Louisiana, with rates of 67.9, 66.4, and 65.4, respectively, had rates higher than the overall rate for the country (64.4). Similarly, the States of the Pacific and the West North Central divisions showed almost uniformly high rates. Of the 10 States in these divisions, only North Dakota and Missouri, had rates lower than the national average.

Once again it might be expected that some of these geographic variations could be attributed to differences between States in variables which are known to affect leukemia death rates, such as urban dwelling (3, 4) and income (5, 10, 11). Coefficients have been calculated for the correlation of the comparative mortality index in each State with the percentage of the white pop-

Figure 1. Mean annual age- and sex-standardized leukemia deaths per 100,000 white persons for each State, 1949-53.

nation of the State classified as urban in 1950, the median income of the white population in 1949, and the number of active non-Federal physicians per 100,000 population in 1949. The correlation with the percentage of urban population was small and insignificant ($r=0.13 \pm 0.14$), but higher correlations were found with both median income ($r=0.27 \pm 0.14$) and density of physicians ($r=0.35 \pm 0.14$). Partial correlation suggested closer association of the leukemia death rate with density of physicians when income was kept constant ($r=0.24$) than with income with physician density constant ($r=0.06$).

The interpretation of these associations is discussed below. It is clear however that they account for only a part of the geographic variation. In sharp contrast to this trend are, for example, the high leukemia rates noted in certain Mountain and other western States in spite of low physician:population ratios, and the

relatively low leukemia rates found in the industrial middle west.

Variations by Age and Sex

The general pattern of the distribution of death rates among States was similar for males and females. The coefficient of correlation between the rates for males and females in the same States was 0.55 ± 0.14 . There is a suggestion that the sex ratio tended to be high in those States with high total death rates ($r=0.26 \pm 0.14$). However, the correlation coefficient is not significant. In general, sex ratios were constant at about 58 percent male from division to division, and, even between States, differences were small (table 1). In the few States in which the proportion of males affected was higher than average, the age trend was not such as to suggest any specific occupational risk.

Numbers are too small for reliable examina-

tion of age trends in the individual States, but divisional age-specific rates are examined in table 2. The rate for each age group for each division is shown as a percentage of the rate for the United States in the same age group. The rates in the Pacific division were particularly high (compared with total United States rates) in the age groups 0-14 and to a lesser extent in the older age groups. In the West North Central division, on the other hand, rates were relatively highest in the older age groups. Two divisions, Middle Atlantic and East South Central, were characterized by relatively high rates in the age groups 15-44.

The different pathological varieties of leukemia have different age and sex trends (12). It may be, therefore, that these age differences in rates for divisions are indicative of variations in the proportions of the different types of leukemia. On the other hand, local circumstances may affect the shape of the age trend through changes in the age-specific risks for a specific pathological diagnosis. No data permitting examination of this question are available.

Secular Changes

To determine whether these geographic patterns have undergone any recent changes, data have been assembled for the 5 years surrounding the census of 1940 (1938-42). As mentioned previously, data on leukemia deaths in individual States are not available by age for this period, and age-standardized death rates can-

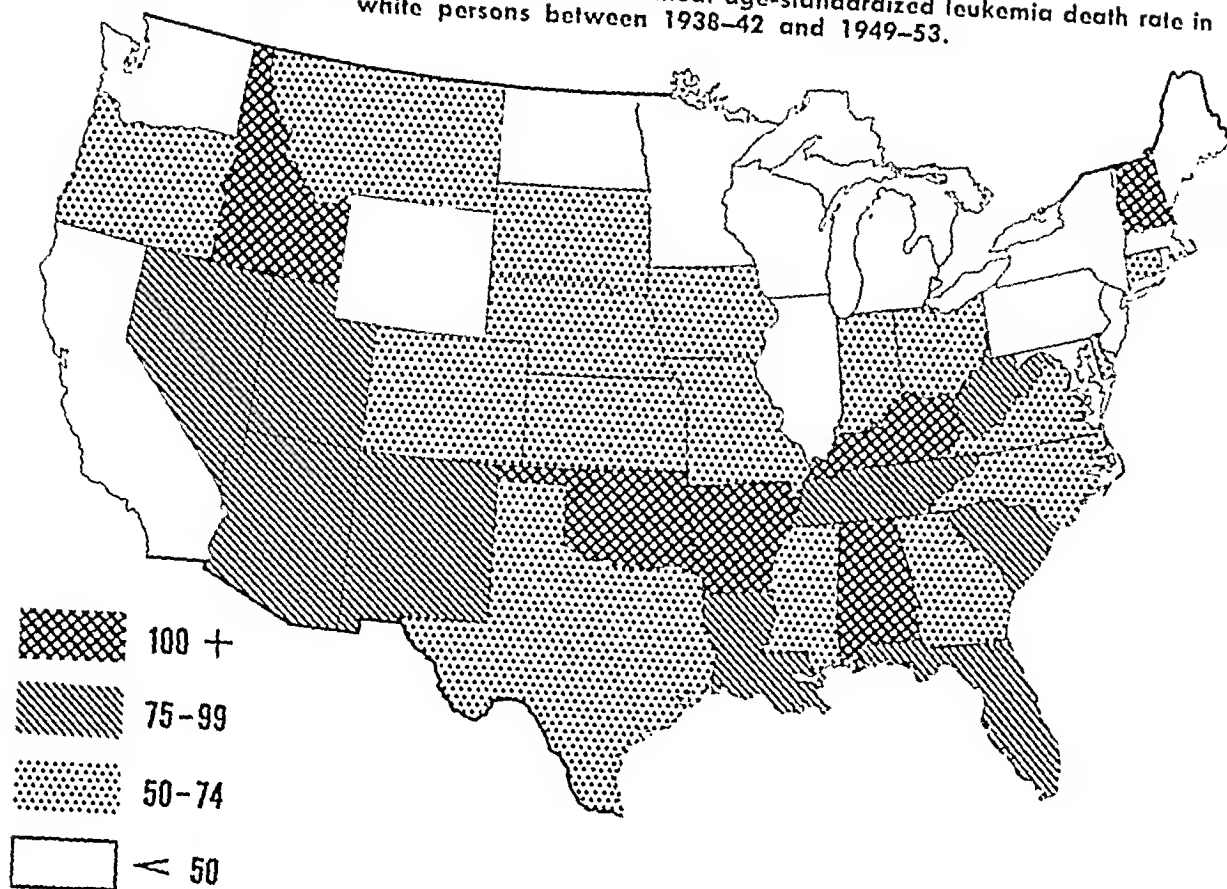

not be calculated. The measurement of secular change in mortality in individual States has therefore been approached in two ways. First, comparative mortality indexes have been calculated for each State for 1938-42, using the total age-specific and sex-specific rates of 1949-53 for the calculation of expected numbers. The increase in the index between 1938-42 and 1949-53 is then expressed as a percentage of the 1938-42 index in the same State (table 1). Second, regression lines have been fitted to the annual crude leukemia death rates in each State separately for the two periods 1938-45 and 1946-53. From these, the regression coefficient is shown as the mean annual increment in table 1. This second method does not allow for age changes in population but gives a crude measure of the rate of increase of leukemia mortality in the two halves of the time period.

In examining the comparative mortality indexes for 1938-42, we may note that the overall pattern is similar to that of the later period, 1949-53. However, there is a suggestion that the physician-income-urbanization complex was more influential in determining leukemia death rates in the early period. Coefficients of correlation of the comparative mortality indexes for 1938-42 with density of physicians and percentage of urban population in 1940 were 0.62 ± 0.14 and 0.60 ± 0.14 , respectively. Data on median income of the white population were not published by State for the 1940 census. The stronger association with the urbanization com-

Table 2. Age-specific leukemia death rates in each division, as a percentage of the United States rate for the same age group, 1949-53

| Age | Pacific | West North Central | Middle Atlantic | East North Central | Mountain | New England | West South Central | South Atlantic | East South Central | Death rate per million, United States |

Figure 2. Percentage increase in the mean annual age-standardized leukemia death rate in white persons between 1938-42 and 1949-53.

plex found in the earlier time period is largely the result of comparatively higher rates in the States in the East North Central division and lower rates in the Mountain States.

The percentage increase in leukemia between 1938-42 and 1949-53 is illustrated in figure 2. The increase in recorded death rates between the two periods was greatest in those areas in which initial rates were lowest. For the southern States, this increase may be interpreted as due to a leveling out of those factors, diagnostic or otherwise, which were responsible for the initial low rates. In two areas, however, Vermont and the Mountain States, such a leveling out cannot be accepted as the whole explanation of the high percentage increase between the two periods since the process has gone beyond the point of equalization. Vermont in 1949-53, for instance, had the second highest leukemia death rate. Similarly, of the five Mountain States with increases above

75 percent, three (Idaho, Utah, and Nevada) had rates in 1949-53 well above the national average.

The probability that the increase in leukemia death rates in certain of the Mountain States is of different origin from that observed in other States with initially low rates is further suggested by the observation that in the Mountain States the rise has affected the second half of the period almost exclusively. This is shown in the two columns of table 1 which give mean annual increments in leukemia death rate for 1938-45 and for 1946-53. In the southern States with large increases, the increase has occurred in both time periods, whereas in Utah, Arizona, Idaho, and Montana the increase has affected the second period predominantly. During 1946-53, two of these States experienced a rate of increase greater than that experienced by any other State in the same or the preceding 8-year period.

In the period 1949-53, the leukemia death rate recorded in certain States of the United States was more than $1\frac{1}{2}$ times as high as that in other States. It is not to be expected that the geographic pattern should be explained in terms of any one variable or influence or even that there should be any one overall pattern. In fact, several separate trends are evident.

First, reference has been made to the partial consistency of the findings with previous reports of high leukemia incidence associated with the social complex which includes urbanization, higher income, better medical care, and more accurate diagnosis. How much of the association of leukemia with this complex is directly attributable to the last component, more accurate diagnosis, is conjectural.

The fact that leukemia death rates in the individual States were more closely correlated with physician:population ratios than with either income or urbanization suggests that diagnostic differences are important. However, the difference between the correlation coefficients for physician density and income was not significant. In addition, while close association with measures of medical care suggests, first of all, differences in diagnostic standards, the possibility mentioned elsewhere (13) that some feature of medical care is itself leukemogenic cannot be overlooked.

It is evident, however, that as a determinant of the geographic pattern of leukemia death rate, the importance of this association has diminished over the time period 1938-53. Correlation coefficients measuring the association in the period 1949-53 were almost half those for 1938-42. This is consistent with the wider distribution of medical care occurring during this period.

A second feature of the geographic pattern is the belt of relatively high leukemia death rates covering the northern half of the United States west of the Mississippi River. This belt is seen in both time periods, although it is more marked in the second. It is clearly not the result of the association with physician density or urbanization discussed in the previous paragraph; in fact it would appear to be evident in spite of this, notably, for example, in Montana and Idaho, both of which have leukemia

death rates of more than 72 per million, and only 94 and 77 physicians per 100,000 population, respectively. Highest rates in this belt were in Minnesota. In fact, in both time periods, Minnesota had the highest death rate of all the States, and by a comfortable margin. Minnesota is, of course, the seat of important medical graduate and postgraduate teaching centers. These could explain the especially high rate in this State on a diagnostic basis, but it could not account for the much wider plateau of high leukemia incidence of which the Minnesota rate is the peak. It should be noted that Minnesota as a whole has a physician:population ratio no higher than the national average.

A third area of interest centers around certain of the Mountain States, particularly Nevada, Utah, Arizona, Idaho, and Montana. The interesting feature here is not so much the present level of the death rate as its recent rate of increase. The leukemia death rate in the area covered by these States almost doubled in the 8 years 1946-53. The rate of increase in this period was high in each of these States, and in two of them (Montana and Idaho) exceeded that experienced by any other State in the same or in the preceding 8 years.

The increase is not explained by changes in the age distribution of the population although there has been considerable migration into certain of these areas during the period concerned. To what extent the increase can be attributed to improvement of diagnostic facilities is uncertain. Examination of the trends for certain other causes of death (duodenal ulcer, diabetes, cancer of the stomach, uterus, and breast), diagnosis of which is also dependent on laboratory facilities, did not reveal any short-term change during this period. Of course, this does not eliminate the possibility of changes in the specific type of facility upon which the diagnosis of leukemia depends.

In 4 of these 5 States, Eisenbud and Harley noted the greatest levels of radioactivity deposited from atomic tests in spring 1952 (14). This fact suggests at first sight the possibility that this source of radioactivity has contributed to the increase in leukemia death rates. The possibility is eliminated however by closer consideration. First, after the initial explosion in New Mexico in 1945, a relatively small one, no

tests were conducted in the United States until 1951 according to the Office of Public Information, United States Atomic Energy Commission. The upward trend in leukemia death rates commenced about 1947-48. Second, a later publication of Eisenbud and Harley showing cumulative radioactive fallout to January 1955 discloses much less correspondence to the pattern of leukemia increases than did the pattern from the single test series recorded previously (15). Third, as reviewed by the same authors, the presently available evidence suggests that the biological effect of fallout in the amounts observed is trivial.

The trend of leukemia mortality in these States in the next few years deserves continued attention.

Summary

United States vital statistics for 1949-53 are used to compare age-standardized death rates from leukemia in the different States and divisions of the United States. Areas are also compared with respect to the increase in leukemia death rate noted since an earlier period (1938-42). The following features are noted:

1. Some of the geographic pattern of leukemia mortality is explicable in terms of the association of leukemia with urbanization, higher income, and better medical care. The importance of this association seems to have diminished in the decade between the two periods examined.

2. Independent of this, there is a belt of high leukemia death rates in States in the northern half of the country west of the Mississippi.

3. In an area covered by five contiguous Mountain States (Nevada, Utah, Arizona, Idaho, and Montana) the leukemia death rate almost doubled in the 8 years 1946-53. Two of these States individually had greater rates of increase during this period than any other State in the same or in the preceding 8 years.

Public Health and the People's Health

By ERNEST M. GRUENBERG, M.D., Dr.P.H.

PUBLIC HEALTH is part of civilization's fight for a better life. With civilization comes an organized, conscious effort to change man's relation to his physical and social environment.

Civilization's fight against disease, specifically, seeks to cheat death for a brief space and to protect man from nonfatal diseases that produce illness. This is done by inventing specific ways of preventing disease. It is strengthened by a social movement to put these inventions to work on a broad scale. The specific public health movement, 100 years old, has created responsible armies of workers and organizations to see that existing inventions are applied and new inventions are made.

The three main forces affecting the level of a people's health are the natural hazards to survival and their distribution, the level of civilization, and the advance of public health.

The history of man's health, which still remains to be written, will describe what is known about the milleniums during which man was at the mercy of natural hazards with little understanding of what they were and with no effective means of acting against them.

Dr. Gruenberg, a member of the technical staff of the Milbank Memorial Fund, New York City, was executive director of the New York State Mental Health Commission from 1949 to 1954. A full version of this paper, here somewhat abridged, was delivered May 2, 1956, in Columbus, Ohio, at the joint meeting of the Middle States Public Health Association and the Ohio Public Health Association. States in the former group are Illinois, Indiana, Iowa, Kansas, Michigan, Minnesota, Missouri, Nebraska, North Dakota, Ohio, South Dakota, and Wisconsin.

The next great period will deal with advancing civilization and the increasing effect of technology on raising living standards and averting famines.

The past century accelerated the advance of public health. Simultaneous with the development of techniques for organized health campaigns, public health movements have become pandemic in Europe and North America. Knowledge has been increasing at a phenomenal rate, giving public health ever more powerful weapons. This new power will raise new responsibilities and require repeated self-examination regarding their nature.

In Ceylon, life expectancy at birth gained nearly a year per year for the 6 years beginning in 1947. A similar rapid rise in life expectancy occurred also in Japan and Puerto Rico while in some other areas, although more favorably situated, populations have not shown such dramatic changes (1).

One implication of these phenomenal successes is that whereas public health formerly represented a late stage in technical development, working effectively to supplement industrialization and to mitigate the harmful consequences of urbanization, new knowledge has made it so powerful that it can precede other forms of social progress.

Another implication is that, while advances in health have often served to assist the process of social development, public health never before had the power to create radically new patterns of disease and mortality, relatively unassisted by general rises in the level of living.

In some places health protection and promotion have become the chief instruments for producing rises in the level of living and in releasing uncounted millions of lives for productive labor.

To the epidemiologist this means that the distribution of organized health movements has become the chief factor in understanding the distribution of many diseases and the pattern of human mortality.

Charting the Future

These and other signs of the power of organized public health are so much on our minds, and respect for its power to effect changes in the people's health is so widespread, that the whole movement seems to be circling in a moderately dazed way in an attempt to find suitable targets on which to strike.

There are dangers in this situation. An example is the mental health movement which, since the war, has come into its own. Although to the administrator popularity may be a matter of envy, to the serious worker it soon becomes a matter of concern.

There is a danger that we come to believe that such popularity must be deserved.

There is a danger that we come to believe our enthusiastic supporters when they claim that we are capable of anything.

There is a danger that we allow ourselves to be held responsible for things we cannot do.

In a time when our power has increased we must remember our duty to inform the public of the sober realities of their health situation. Public health workers have always been long on faith and enthusiasm and at times short on facts and self-criticism. With the powerful weapons that are now available and the widespread faith and enthusiasm that are evident, the movement needs to strengthen its balance wheel of facts and self-criticism.

The suggestion that the next great chapter in public health should be centered on positive health and medical care can be misleading.

Medical care has become a powerful tool for reducing disability and postponing death in the presence of certain diseases. Furthermore, everyone has the right to expect the best available medical care when he is ill.

But, from the public health point of view, every case that comes to medical care represents a failure of a movement whose objective is to keep illness from occurring. Obviously, physicians in this country keep very busy in

spite of preventive medicine's great successes. Public health will not be doing its job unless it tackles the causes of morbidity and mortality which still plague the people.

Attacking Preventable Diseases

First, we must do what we know how to do. There are some vital gaps in civilization's battle against disease.

We have not found practicable ways of preventing all preventable diseases, diseases for which the technical means of prevention are well established. The great progress on which we compliment ourselves has affected a pitifully small percentage of the world's population. Malaria alone, a completely preventable disease, is still a great killer.

It is not only abroad that these gaps are to be found. Malnutrition, tuberculosis, venereal disease, excess infant and maternal mortality, and inadequate medical care and rehabilitation are often found in the United States in particular neighborhoods and sections of the population. Infant mortality in New York City, for example, is as high as 35 per 1,000 live births in 4 districts and as low as 17 in some districts of the city (2).

Retarded populations in this country suffer not only from poor health but also from poverty or ignorance. If public health is going to continue to work for the improvement of the people's health, it will concentrate on these populations.

One useful approach is the examination of patterns of differential mortality rates. Although we are working toward consistency and constancy in statistics on occupation and mortality, England has issued tabulations of mortality by social classes for several generations. While we have failed, perhaps, to be impressed by the fact that the standardized mortality ratio for the least favored populations in England and Wales is twice as high as for the most favored, we should be impressed by the fact that age-specific death rates for adult males are higher for each comparable age group in this country than in England. And we should be even more impressed by the fact that standardized mortality ratios vary more by occupational groups in this country than in England (3).

This is not the place to recommend solutions. It is important to recognize that these problems exist and that the measures available point unmistakably to unfinished business for public health.

Some of the specific areas for attention which might lead to a reduction of some of these differentials are well known. To list a few:

- Nutrition is not optimal for the entire population.
- Housing is not sanitary or safe for all.
- Fluoridated water is not yet available to most urban families.
- Medical care is not readily available to those who need it most. In particular, the aged frequently cannot afford the high costs of medical and nursing care. Often they do not receive the detailed attention that medical science can offer to preserve remaining functions.

Dr. Haven Emerson once propounded the theorem that the first step in public health occurred when man rose up out of his own filth. Although mankind has long since passed that early stage, it now finds itself surrounded by man's collective filth in air and water. The present movement to rid rivers, coasts, and city air of man-made pollution has scored some signal successes on a few small fronts. The staggering proportions of the problem and its implications for civilized life illustrate the old proposition that public health cannot "go it alone" but must act as a center of technical and community leadership for all the forces interested in the people's health and welfare.

Using Knowledge Fully

There are also some new frontiers for public health. Four major health problems—mental diseases, arteriosclerosis, cancer, and the common cold—serve to remind us that there are still diseases we do not know how to control and that there are some public health objectives we would like to reach but do not know how.

A proper humility before the forces of nature obliges us to recognize that we are powerless to prevent these conditions in the mass and that medical science can do little to change the course of most of these diseases once they are started on their way.

Our first obligation as professional health

workers is to know the facts. Our second is to communicate them intelligibly to the people we serve. Our third is to devise and execute schemes to put the limited knowledge we do have to effective use.

For example, though many prevention programs have been instituted in the mental diseases, most have ignored established knowledge.

In one State the mental health program is centered on human relations in the health department and in the schools. Some cases of pellagra psychosis occur each year, but the program does not consider control of these preventable cases to be its function. Nor does it concern itself with the preventable cases of neonatal brain hemorrhage caused by Rh incompatibility. Available knowledge strongly suggests that young infants and preschool children require stable family life for healthy personality development, but the program does not seek to prevent preschool children from being housed and fed in institutions or in a series of foster homes.

It would seem that the first item on any public health program must be the elimination of preventable instances of morbidity and mortality. But the bulk of mental illness today cannot be prevented by known techniques.

Can we shorten the duration of some mental cases? There is some reason for hope in this direction. Acute depressions in the involutional years are sensitive to shock treatments. Some neuroses of childhood seem to be relieved by quick responses by the adults in the child's environment. Mental deficiency is partly treatable.

Can we reduce the disability which mental illness produces? In many instances, yes. We know that we overhospitalize mental illnesses in a wanton fashion. We know that with good medical care many chronically ill people can live slightly impaired lives instead of hospitalized lives.

Programs which emphasize positive mental health often distract attention from the pluses and minuses in our knowledge. Mental health programs emphasize child guidance clinics, but the clinics generally prefer to see chronic neuroses rather than to try to see an acute neurosis while it is acute or to help a neglected infant. Programs emphasize building more hospitals

when the use of mental hospitals has become excessive. Psychiatrists are trained to treat the least ill rather than the chronically ill whose disability they could often reduce. Education programs are called preventive even when there is no real reason for believing they have any important preventive effects.

Avoiding Illusions

Parent education is necessary within reason, and child guidance clinics, adult psychiatric clinics, mental hospitals, psychotherapy for neuroses are both necessary and valuable. Perhaps the emphasis on these activities in existing mental health programs comes from an illusory kind of thinking. Some of these illusions have become our standard ways of avoiding unpleasant realities. To describe a few:

"Where there is a will, there is a way." This is true about carrying out an activity, but it is not true about achieving an objective. You may shout across the ocean with great will, but without a radio you will not be heard. You may educate parents with gusto, but you cannot be sure you have prevented any mental disease.

"Early diagnosis and treatment is secondary prevention because it shortens disease or reduces disability." This is a simple inversion of the true proposition that secondary prevention consists of early diagnosis and effective treatment. Ineffective treatment doesn't help arteriosclerosis. There is no real reason to think that early diagnosis and treatment can reduce morbidity or mortality in this disease.

"Activity is good." It isn't always.

"If one clinic doesn't help, get two." If one super anticold pill doesn't stop your cold, take two. If two don't help, take three.

"Doctrine of signs and names." This illusion consists of the belief that the name of an agency describes its effects. To stop the common cold, set up an anticold commission and give it the assignment of stopping colds. If the incidence of colds goes up the first year, enlarge the agency the second. After staff has obtained tenure and the rates are still rising, have a shakedown, change the name, and bring in a director who has impressive qualifications. The chances are that you will get a competent staff who think the common cold is a bad thing,

who will probably find ways of reducing the amount of headaches and coryza, who may produce some skin-tanned children by lighting classrooms with ultraviolet lights, and who will increase the sale of nasal paper tissues, and decrease the sale of pocket handkerchiefs. They will keep busy and do some useful things, but they probably won't have much effect on the number of people who suffer from the common cold.

The reason is obvious: They don't have the knowledge; they don't have the techniques. In spite of good scientific training in tailoring means to fit ends and in learning to recognize facts as facts, the best intentioned of us get carried away by the desire to effect changes, to slay the wicked dragons. When ignorance or difficulties frustrate, we switch goals and develop formulas for self-justification.

These are some of the current thoughts of one mental health worker regarding the future of public health. The objective of public health work is to control disease. The value of public health activity depends entirely on its success in achieving that objective. As techniques become more powerful and as health organizations become larger, the responsibility for keeping track of our successes and failures becomes greater.

The successes of the past can guide us, but the successes of the future will be even greater and will demand as much originality and steadfastness from public health workers.

The people's health is becoming increasingly more subject to the control of public health, but the people's health still manages to vary in ways which public health has not yet been able to control.

Epidemiological Methods and Inferences in Studies of Noninfectious Diseases

By ABRAHAM M. LILIENFELD, M.D., M.P.H.

DURING THE PAST FEW YEARS, the epidemiological approach has been applied increasingly to the study of noninfectious diseases, such as cancer and heart disease. Various methods of study have been used, and various inferences have been derived from the observations. In several instances, such as the relationship between lung cancer and cigarette smoking, the inferences have provoked considerable discussion. This in turn has led to consideration of certain selected aspects of the conceptual framework of these inferences (1-5). However, there still exists a need for a more general review of the methodology and of the considerations that may influence the derivation of inferences from the observations. This paper intends to provide such a review, although it does not pretend to cover all aspects of the subject. This review may give perspective on some of the issues involved. It may stimulate further discussion and investigation so that the methodological problems confronting us can be gradually resolved.

Uses and Sources of Data

Epidemiology may be defined as the study of the distribution of a disease or condition in a population and of the factors that influence this distribution. Thus, the epidemiologist is in-

terested in variations in frequency of diseases by such characteristics as age, sex, race, social class, and occupation. This knowledge is useful for the following reasons:

1. It permits the development of hypotheses concerning etiological factors. Thus, if the disease is observed to be more frequent in a particular population segment than in others, hypotheses are developed to explain this increased frequency.

2. It can be used to test hypotheses developed in the laboratory or clinic. It is important to determine if an etiological hypothesis, based on laboratory or clinical observations, is consistent with the known distribution of the disease in human populations; to the extent that it is not consistent, the hypothesis will have to be modified.

3. It provides the scientific basis for public health administrative measures to control the disease. Even if knowledge of etiological factors is inconclusive or erroneous, epidemiological data may still be used for such control measures as case finding and the early detection of affected individuals.

The present discussion will be concerned principally with the use of epidemiological observations to elucidate etiological factors.

An epidemiological study provides data from which may be derived a series of statistical associations between a disease and various characteristics of the population. From this pattern of statistical associations, biological inferences may be drawn. The totality of the associations and the inferences constitutes the epidemiology of a disease. Thus, the epidemiological method consists of two stages: first, the

Dr. Lilienfeld is chief of the department of statistics and epidemiology, Roswell Park Memorial Institute, Buffalo, N. Y., and associate professor of preventive medicine and public health, University of Buffalo Medical School.

determination of one or more statistical associations; second, the derivation of inferences or hypotheses from the series of associations.

Two distinct types of studies are used to determine statistical associations: studies of demographic data and studies of individual history data. The latter may be divided into three general categories: retrospective studies, prospective studies, and experimental studies. Of these latter, only the first two will be examined in this review. Both of these concern observations of naturally occurring phenomena, and the investigator has no direct control over other possible factors that may influence the associations so determined. Properly designed human experiments are the only certain way of establishing an association between a disease and a characteristic. However, opportunities for carrying out such studies are rare.

Demographic Studies

Demographic data are obtained principally from routinely collected vital statistics reports. They provide information concerning the distribution of either mortality or reported cases in time, by age, sex, race, social class, and other characteristics. Such data may differ from data based on individual histories in several respects. For example, demographic data may show an association between two events in time, whereas individual history data may show that an individual with a certain characteristic also has another characteristic; the latter is more likely to reflect a biological relationship. Also, certain demographic data, such as socioeconomic data, may deal with average characteristics of a group of individuals rather than with the characteristics of each individual.

Associations based on demographic data are of value in furnishing a lead for more detailed investigations. However, they must be interpreted with caution because of questions concerning the accuracy of death certification, reporting practices, and the like. General familiarity with demographic data makes further discussion unnecessary.

Retrospective Studies

The retrospective approach consists of obtaining a group of individuals with the disease,

which we shall call B, and determining the percentage of these individuals who have the characteristic A, which is considered a possible etiological factor. This frequency is then compared with a similar frequency in a so-called control or comparative group of individuals without the disease. If the frequency of A is higher among those with B than among those without B, an association is said to exist between A and B. In such studies, the cases (with B) and the controls (without B) can be selected in several ways.

Hospital Populations

Most frequently, both the cases and the controls are obtained from hospital populations. Practically all the retrospective studies indicating an association between lung cancer and cigarette smoking have been hospital studies. Control groups usually consist of patients with other diseases admitted to the same hospital or hospitals. This method's popularity results from the ease and inexpensiveness with which data can be obtained. In evaluating this method, several factors must be considered and their relative importance judged by the investigator.

Probably the most frequent problem encountered in studies of hospital populations results from the influence of what is termed "selection." In this connection, it will be helpful to distinguish "sampling selection" and "biological selection." When selection is discussed in this type of study, sampling selection is usually meant. The question of biological selection will be considered later. Berkson has shown the possibility of obtaining a spurious association of A and B because of sampling selection resulting from differential rates of admission to the hospital of individuals with A, those with B, and those without B (6). However, Berkson (6) and Kraus (7) have also indicated that if characteristic A does not influence the admission of individuals to the hospital, the likelihood of a spurious association is negligible.

Decision as to whether A does or does not influence admission to a hospital may at times be difficult. To a large extent, we are dependent on the judgment of the investigator and on our general knowledge of the specific situation,

making evaluation of the results difficult. In many instances we may feel that a specific characteristic A does not influence hospitalization, but this may result from ignorance of all of the related variables involved. For example, if we are interested in determining a possible relationship between eye color and a specific disease, and we find an association between blue eyes and a disease in a hospitalized series of cases and controls, it does not appear likely that individuals with blue eyes would be selected for hospitalization. However, if we are in a community in which the ethnic group with blue eyes is predominantly in the lower social strata and if social class influences hospitalization, it is possible that sampling selection may operate to such an extent as to result in a spurious association of a disease with blue eyes.

In determining the importance to be assigned to the influence of sampling selection, another factor that must be considered is the strength of the observed association. In the extreme case, if we find that all the B individuals have A and all the non-B individuals do not have A, it would be very difficult to deny the existence of an association between A and B, unless the characteristic A exerts an unusually large influence on the chances of hospitalization. Unfortunately, most associations are not this strong. Hence, it may be helpful to judge the relative importance of sampling selection by determining arithmetically how much of an association could be expected for varying degrees of sampling selection; we shall illustrate this in our discussion of prospective studies. If the degree of the association is much greater than could be expected after taking into account what may be considered a reasonable influence of sampling selection, the association may be more readily accepted. Objections to this approach might be raised since it is not as clear cut as is usually deemed desirable. However, an element of judgment is always present in the evaluation of any set of data, regardless of the source.

In many hospital studies, confidence in an observed association may be increased by the presence of internal evidence. For example, if several non-B groups, each with a different disease or condition, are compared with the B group and the results with regard to character-

istic A are similar, confidence in the existence of an association can be greater than if only one non-B group is used. Also, confidence may be greater if there is a relationship between the frequency of B and the amount of A, provided that A can be quantified. In general, the more ways in which an association can be shown, the greater can be our confidence that it is a real one and not a result of such a disturbing factor as sampling selection.

Clearly, the determination of a statistical association by hospital studies poses many difficult problems, since an interpretation concerning the existence of a relationship depends largely on the investigator's judgment regarding the plausibility of other explanations for the observed association. A point frequently overlooked is that disturbing factors actually may operate in the opposite direction so that a true association is obscured as a result of sampling selection. One might argue that this situation would occur only if the association were not a very strong one and, therefore, not very important. However, in seeking clues about etiological factors, no possible associations should be overlooked.

Controls From General Population

A modification of the hospital studies is the use of a control group selected from the general population and matched with the hospitalized cases according to certain characteristics. Usually, such a control group consists of individuals who reside in the same area and are similar in age, sex, and race to the hospitalized cases. A matched population control may diminish some of the difficulties resulting from the possible disturbing effect of sampling selection, but it is not completely clear as to how much really is accomplished. It is principally on intuitive grounds that such a control is regarded as better than a hospital control.

In some situations it is possible that a matched population control group is worse than a hospital control group. If characteristic A is another disease or condition requiring medical diagnosis for its determination, the objection could be raised that matched population controls differ from hospitalized patients with regard to the amount of medical care received. For example, in studying the association of can-

cer of the cervix with diabetes, we would carry out a retrospective study with hospitalized cervix cancer patients from whom we obtain a history of diabetes. A matched population control may be completely inadequate for comparison with the patients since the patients and controls would differ with regard to the amount of medical care received, and, therefore, the matched control group may actually have a larger proportion of undiagnosed cases of diabetes. This situation will arise if the information concerning diabetes is obtained by interview. However, if the presence of diabetes is determined by examination, this difficulty will not be encountered. Consequently, if it is necessary to obtain the required information by interview it may be preferable, in certain instances, to use hospitalized patients as the controls.

A control group for comparison with a hospital case group can also be obtained by selecting a random sample of the population and adjusting for differences in sex, race, age, and other variables by available statistical techniques. The question of whether to use matched or randomly selected controls has been discussed most recently by Cochran (8) and Greenberg (9). Apparently, each method has certain advantages and disadvantages, with the random sample having a slight edge. The problem of diagnostic comparability mentioned in the case of matched population controls also occurs with regard to a random sample control group.

Cases and Controls From General Population

To avoid problems imposed by sampling selection, the best approach would seem to be to obtain a sample of all cases in a community and to select either a matched or random sample of the general population as a control group. However, when samples of the general population are used, the cases and controls are again not comparable from the viewpoint of medical care. Consequently, if we are interested in determining the frequency of a characteristic that is influenced by the amount of medical care received, a more appropriate method of determining this characteristic than interviewing must be used. Selection of cases and controls from the general population appears preferable to other methods of selection in that, with this

method, it is least necessary to depend on judgment concerning the relative weight to be assigned to the influence of sampling selection and other possible disturbing factors.

It is remarkable that this kind of study has not been used in epidemiological investigations of noninfectious disease more frequently than it has. The only drawback is that such studies are more difficult, expensive, and time-consuming than studies of hospitalized cases. Despite the obvious advantages, it must be admitted that theoretically this method does not avoid all possibility of sampling selection, since it might be argued that "all cases" includes only "all known cases" and undiagnosed or asymptomatic cases may have been selectively omitted with respect to the variable under study. After hospital studies have indicated the existence of associations, it would appear more profitable to expend funds and energies on confirmation by general population studies than to continue repeating hospital studies ad infinitum.

Additional Considerations

In retrospective studies, information is usually obtained by interview. Interviewing as a method of measurement has a fair amount of error, which, among other things, results in a certain amount of misclassification of individuals with and without the characteristic under study. Bross has pointed out that the ability to detect differences in the frequency of a characteristic in two groups decreases with increasing amount of misclassification (10). Thus, in retrospective studies, where there always will be some degree of misclassification, there is a certain risk that a true association will not be detected. This lack of sensitivity has not been sufficiently realized. In addition, the possible intrusion of subjective bias, both conscious and unconscious, must not be overlooked. When a history of a characteristic is obtained and the interviewer knows which individuals are the cases and which the controls, it is difficult to be certain that the differences observed between the two groups are not the result of subjective bias.

Retrospectively obtained data can be further evaluated by noting if the results are consistent with those obtained by demographic studies. Consistent findings will increase the confidence in the existence of observed associations, but it

is difficult to determine the degree by which such confidence will or should be increased.

Prospective Studies

In prospective, or followup, studies groups of individuals with and without the characteristic A are obtained and followed for a definite period of time to determine the risk of developing B when the characteristic A is present as compared with the risk when it is absent. These groups may be selected from the population in either a random or a nonrandom manner. Several practical considerations must be taken into account in the actual process of selection. For example, if the characteristic A is very frequent in the population, a completely random sample of the population may not be the most efficient method of selecting the two groups, since the number of individuals without A in a random sample may be too small. To increase the number of individuals without A, it may be necessary to select more of them from the rest of the population by matching with the individuals with A in the random sample. A similar situation may occur with an infrequent characteristic. If we are interested in prospectively studying the association of diabetes with cancer of the cervix, it would probably be best to select a random sample of diabetic patients in the community. Then we could select either a matched control group of nondiabetics or a random sample of the entire population from which we could obtain a control group of nondiabetics by further sampling and perhaps matching. In general, the method of selection depends largely on the particular characteristics being studied.

If a nonrandom sample is used, sampling selection may be a disturbing factor. Berkson indicated this possibility in an analysis of some of the prospective studies of the association of cigarette smoking with lung cancer (11). In these studies, nonrandomly selected groups of smokers and nonsmokers were followed for a certain period of time, and it was observed that the death rate from lung cancer was higher among smokers than among nonsmokers. By numerical illustration, Berkson demonstrated that sampling selection may produce a spurious association. From other sources, he obtained

estimates on the frequency of smokers in the population. This frequency was different from that in the study population, indicating that sampling selection had taken place. Berkson then demonstrated that this degree of sampling selection would result in a lung cancer death rate among smokers that was 1.5 times that found among nonsmokers. However, according to a report on the prospective studies by E. C. Hammond, the observed rates among smokers in the 4 age groups studied are from 3 to 17 times the rates observed among nonsmokers. For such a difference to be a result of sampling selection, it would be necessary to assume a degree of selection that apparently was not present in these studies. This example is presented to indicate the need for evaluating the strength of the association in relation to the degree of sampling selection that could have occurred. As in the case of retrospective studies, judgment must be exercised in the evaluation of the data.

The followup method of study has several advantages. First, it provides a direct estimate of the risk of developing the disease B when A is present, whereas in the retrospective method this can only be obtained indirectly. It is not certain how advantageous this really is when the major objective is to try to determine possible etiological factors. But some investigators prefer direct rather than indirect estimates. Second, a prospective study decreases the risk of subjective bias, provided that the criteria and procedures are established in advance. Third, it decreases the likelihood of misclassifying individuals with and without the characteristic. For example, in determining the relationship of artificial menopause to female breast cancer retrospectively, we are dependent on a history of artificial menopause. In a certain proportion of cases the history would be erroneous. However, in a prospective study we would start with individuals who currently have an artificial menopause; therefore, there would be no misclassification of these individuals. This tends to increase the chances of finding an association if one actually exists.

Observations to Increase Confidence

In either a retrospective or a prospective study, confidence in observed associations may

be increased by including individuals who had characteristic A initially and then lost it. For example, in the studies on cigarette smoking and lung cancer, there were individuals who had been smokers and then had become nonsmokers. Therefore, it is possible not only to compare cigarette smokers and nonsmokers with regard to the risk of developing lung cancer, but also to determine the risk for individuals who were smokers and then became nonsmokers. E. C. Hammond reported that for this group the risk of lung cancer is less than for those who remained smokers. This is a valuable observation since it is less likely that such factors as sampling selection are responsible for this type of an association.

Additional confidence in the observed associations may be obtained also by comparing the affected groups and controls or those with a characteristic and without a characteristic with regard to as many other variables as possible. On the question of smoking and lung cancer, it would be of considerable interest to see if smokers and nonsmokers and if the lung cancer cases and the control groups are alike with regard to such characteristics as alcohol consumption, family size, occupation, and the like. Except for occupation, such comparisons are not yet available. This is one major methodological criticism that could be leveled at lung cancer studies. The more characteristics with regard to which the groups are similar, the more certain can one be that the difference with regard to smoking habits is real. However, the present level of epidemiological knowledge sets a limit in determining the characteristics to be selected for comparison. There is a risk of stating that the two groups are comparable with regard to characteristics that may eventually turn out to be unimportant. As knowledge of the epidemiology of a disease increases, it can be used continuously to evaluate more properly previously determined associations.

Causality in Biological Phenomena

After a statistical association has been ascertained, we would like to make some sort of an inference as to whether a cause and effect relationship exists between the disease and the associated characteristic. Before discussing fac-

tors that influence this type of inference, we need to consider the concept of causality.

In medicine and public health it seems reasonable to adopt a pragmatic concept of causality. One major reason for determining etiological factors of human disease is to use this knowledge to prevent the disease. Therefore, a factor may be defined as a cause of a disease, if the incidence of the disease is diminished when exposure to this factor is likewise diminished.

This concept is not as logically rigorous as the more formalistic one held by some investigators, which requires evidence indicating that a factor is both a necessary and a sufficient condition for a disease before it is incriminated as a cause. In biological phenomena, both these requirements do not have to be met because of the existence of multiple causative factors. For example, in tuberculosis, the tubercle bacillus is a necessary but not a sufficient condition for tuberculosis. Other additional factors included under the term "susceptibility" are important. In other infectious diseases, the micro-organism is a necessary factor but not always a sufficient one. In diseases generally considered as noninfectious, such as cancer, the concept of causation may have to be broadened further, since one particular etiological factor may not even be a necessary one because of the probable existence of multiple causative agents.

Actually, in both infectious and noninfectious diseases the differences in these two concepts of causality depend upon the frame of reference. To illustrate, the cause and effect relationships with multiple etiological factors, labeled A_1 , A_2 , A_3 , and so forth, each acting independently, are presented in the accompanying drawing. These factors can be looked on as producing a change

in B at a cellular level. The changed cell B could then develop into C, the disease. Clearly, the cellular change in B can be considered as the necessary and sufficient condition for the disease C. Therefore, to meet the more rigorous definition of causality, the biological mechanisms relating A to B and B to C must be determined. Pragmatically, however, the determination of each of the A factors is important, since attention must be focused on these to be able to apply preventive measures.

The derivation of causal inferences from observed statistical associations is difficult because of the inability to eliminate the possible effect of another variable that may influence both the characteristic A and disease B. For example, in the cigarette smoking-lung cancer relationship, it is possible to postulate the existence of another factor that causes a person to smoke and also causes lung cancer. Or perhaps there exists some constitutional factor among non-smokers that decreases their risk of developing lung cancer. The latter viewpoint is not unreasonable since there is a tendency for persons participating in athletics not to start smoking at that time of life when smoking habits are developed. Such individuals may be constitutionally hardier as shown by their participation in athletics, and perhaps this constitutional factor decreases their risk of developing lung cancer. If such relationships exist, they would result in a statistical association without a causal relationship. This situation may be termed biological selection since individuals are selected for both the characteristic and the disease by a third mutually related factor. Similar problems are encountered in many fields, such as genetics and sociology (12, 13).

Biological Considerations

One important biological consideration that may influence the derivation of causal inferences concerns the ability to experiment. If one can select samples of individuals from a population and randomly allocate them to two groups, one with and the other without the characteristic, and the statistical association continues to exist, the randomization procedure has taken into account most, if not all, of the other related variables. Such well-controlled

experiments had a major role in establishing a causal connection between fluorides in drinking water and reduction in dental caries. However, experimentation is not usually feasible in most human diseases.

Another influential factor is the degree of the observed association. If the statistical association is very strong, it is less reasonable to suppose that a mutually correlated third factor was involved. Admittedly, a 100 percent association does not completely eliminate the possible existence of a third factor, but it does make such a possibility more unlikely. Here again, such a situation is rarely encountered.

Probably the most important consideration is whether or not the association is consistent with existing biological theory. If a statistical association makes biological sense, it is more readily accepted than one that is at the moment not capable of biological explanation. By "biological sense" we mean that the mechanisms leading from the characteristic A to the disease B fit into some biological (physiological or pathological) framework. If this framework exists, it was probably derived from other kinds of observations; therefore, it is intuitively felt that the association has been verified by other, independent observations.

This type of reasoning can be illustrated from studies of pregnancy experience and neuropsychiatric disorders in childhood (14). In these studies an association was demonstrated between certain maternal factors during pregnancy and the development of such disorders as cerebral palsy, epilepsy, and mental deficiency in the offspring. This association fits into a reasonable biological framework since the mechanisms of such relationships are readily conceived. These same factors have been shown to produce anoxia in the fetus, and anoxia may result in damage to the brain, which, in turn, is logically related to the disorders mentioned. Consequently, the statistical association is readily acceptable as a causal hypothesis.

On the other hand, in the association of cigarette smoking and lung cancer, no direct links between cigarette smoking and cancer have been worked out. There is evidence indicating that environmental agents are important in the etiology of cancer, which does strengthen the hypothesis that cigarette smoking and lung

cancer are causally related. It also seems more reasonable to accept cigarette smoking as a causal factor than the application of a certain ointment to one's feet or the ingestion of alcohol, since cigarette smoke does come in contact with the site of lung cancer. But the biological plausibility of a causal hypothesis on these two bases is not of the same order as in the case of pregnancy factors and neuropsychiatric disorders.

There are historical instances in which a statistical association did not originally conform to existing biological concepts. As advances in knowledge changed the biological concepts, these new concepts were found to be consistent with the previously observed association. Conversely, there have been instances in which the statistical association was interpreted as being consistent with existing biological concepts, but later the interpretation of the association was found to have been erroneous.

The classical example of the first situation is afforded by Snow's investigation of cholera (15). Snow observed an association between the ingestion of polluted water and the development of cholera during 1819-54. At that time, prior to the establishment of the germ theory of disease, the accepted etiological hypothesis for cholera was the miasmatic theory. Snow's observations were not generally accepted since they did not conform to the miasmatic theory. After the germ theory of disease was established, Snow's statistical association was consistent with the germ theory, and, hence, it was accepted. Thus, the prevailing biological opinion was erroneous whereas the inference made from the statistical association was not.

The second situation is exemplified by Farr's observation of an association between elevation of residence above sea level and cholera mortality in London (16); his data, for 1848-49, are shown below. With increasing elevation, there was a decline in cholera mortality. This association was consistent with the miasmatic theory and was interpreted as confirmatory evidence. When the miasmatic theory was replaced by the germ theory, this association was still reasonable since elevation was in turn inversely associated with the etiological factor, polluted water.

| <i>Elevation above sea level, in feet</i> | <i>Deaths in 10,000 inhabitants</i> |
|---|---|
| Under 20----- | 162 |
| 20-40----- | 65 |
| 40-60----- | 34 |
| 60-80----- | 27 |
| 80-100----- | 22 |
| 100-120----- | 17 |
| 340-360----- | 7 |

One other biological consideration is the role of animal experimentation. There is a widespread feeling that, if a statistical association is confirmed by an animal experiment, definite proof of a cause and effect relationship in humans is established. It is important to realize that applications of the results of animal experiments to human situations are fraught with danger. If we are concerned with such disturbing influences as sampling and biological selection in studies of humans, we should be so much the more careful of basing conclusions on results of animal experiments. Confirmation by animal experimentation increases the biological reasonableness of a causal inference. It also provides an animal model by which possible biological mechanisms may be elucidated, thereby indicating how and where such mechanisms might be investigated in humans. But, in interpreting results from animal experiments, it is important to distinguish between definite proof and increased biological plausibility.

Nonbiological Considerations

Certain nonbiological considerations may influence an individual's attitude toward acceptance of a causal inference. These concern the decisions that are made relative to the course of action to be taken when an inference is accepted. They reflect the outlook, background, and administrative responsibilities of the individual. For example, a research scientist, without any direct responsibility for the health of a population, might require a very high degree of plausibility before accepting a causal inference and recommending definite administrative action. On the other hand, a health officer, directly responsible for the health of a population, may accept a lower degree of plausibility as sufficient to warrant preventive action. He may therefore accept a causal inference when he thinks that it has a good chance of being correct but before it is definitely proved.

Such considerations usually play a role after the statistical association is established and before a causal relationship is definitely proved. During this period, causal inferences are regarded with varying degrees of plausibility. It is helpful to consider the possible relationships between courses of action and degrees of plausibility, as follows: At the first level, the evidence is considered sufficiently suggestive to warrant further investigation. At the second level, the evidence is considered sufficient for recommending attempted preventive action. At the third level, the evidence is considered sufficient to state that a causal inference has been proved, and this causal hypothesis is included in our body of scientific knowledge. There is an interaction between the degree of plausibility with which an inference is regarded and the actions based on these inferences.

It seems that the present controversy over the inferences from the cigarette smoking-lung cancer association is largely concerned with the degree of plausibility. It is generally agreed that the evidence is sufficiently suggestive to warrant further investigation. At the other extreme, there is general agreement that the evidence is not sufficient to warrant a statement that a causal hypothesis is definitely proved; this level will not be reached until the detailed biological and chemical mechanisms have been worked out. At present, the major issue is whether a causal inference is sufficiently plausible for a public statement that cessation of cigarette smoking would diminish the risk of acquiring lung cancer. Since the degree of plausibility cannot be directly assessed, differences of opinion naturally develop.

In evaluating these decision levels, it is important to keep in mind that in many instances action based on a statistical association could be successful even though it is interpreted incorrectly from a biological viewpoint. To illustrate this we recall Farr's observation of the association of decreasing cholera mortality with increasing elevation of residence above sea level (16). If the health officer had recommended that people living in the lower-lying districts of London move to the higher districts, a decline in cholera mortality would probably have resulted, although such action would have been based on the erroneous miasmatic theory.

Summary

Increasing use of the epidemiological approach in the study of noninfectious diseases emphasizes the need for considering the conceptual framework of such studies. Epidemiological studies are composed of two stages: first, the determination of statistical associations between a disease and various population characteristics; second, the derivation of biological inferences from the pattern of associations. Both the associations and inferences constitute the epidemiology of the disease.

Statistical associations may be determined from demographic data or from individual history data. The latter may be obtained from retrospective studies, prospective studies, or experimental studies. In these studies, characteristics of a group of cases are compared with those of one or more groups of controls. Cases and controls may be selected by various methods, each of which has advantages and disadvantages.

In general, leads to the existence of statistical associations come from individual history studies of hospital populations or from demographic data. The associations so suggested require confirmation by retrospective studies of adequately selected samples of cases and controls from their respective populations. Whether or not prospective studies are necessary depends largely on the kind and strength of the association. The method of carrying out a prospective study depends on the nature of the characteristics and the disease under investigation.

In the derivation of causal inferences from observed statistical associations, certain biological and nonbiological factors are influential. Among the biological factors are the ability to conduct human experiments, the strength of the association, the role of animal experimentation, and the prevailing biological concepts. The latter is the most important. Snow's and Farr's observations on cholera are illustrations of the interaction between biological theory and the interpretation of statistical associations. A nonbiological factor is the course of action resulting from the degree of plausibility with which a causal inference is regarded. This factor, directly or indirectly, influences an in-

cancer are causally related. It also seems more reasonable to accept cigarette smoking as a causal factor than the application of a certain ointment to one's feet or the ingestion of alcohol, since cigarette smoke does come in contact with the site of lung cancer. But the biological plausibility of a causal hypothesis on these two bases is not of the same order as in the case of pregnancy factors and neuropsychiatric disorders.

There are historical instances in which a statistical association did not originally conform to existing biological concepts. As advances in knowledge changed the biological concepts, these new concepts were found to be consistent with the previously observed association. Conversely, there have been instances in which the statistical association was interpreted as being consistent with existing biological concepts, but later the interpretation of the association was found to have been erroneous.

The classical example of the first situation is afforded by Snow's investigation of cholera (15). Snow observed an association between the ingestion of polluted water and the development of cholera during 1819-54. At that time, prior to the establishment of the germ theory of disease, the accepted etiological hypothesis for cholera was the miasmatic theory. Snow's observations were not generally accepted since they did not conform to the miasmatic theory. After the germ theory of disease was established, Snow's statistical association was consistent with the germ theory, and, hence, it was accepted. Thus, the prevailing biological opinion was erroneous whereas the inference made from the statistical association was not.

The second situation is exemplified by Farr's observation of an association between elevation of residence above sea level and cholera mortality in London (16); his data, for 1848-49, are shown below. With increasing elevation, there was a decline in cholera mortality. This association was consistent with the miasmatic theory and was interpreted as confirmatory evidence. When the miasmatic theory was replaced by the germ theory, this association was still reasonable since elevation was in turn inversely associated with the etiological factor, polluted water.

| <i>Elevation above sea level, in feet</i> | <i>Deaths in 10,000 inhabitants</i> |
|---|---|
| Under 20..... | 102 |
| 20-40..... | 65 |
| 40-60..... | 34 |
| 60-80..... | 27 |
| 80-100..... | 22 |
| 100-120..... | 17 |
| 310-360..... | 7 |

One other biological consideration is the role of animal experimentation. There is a widespread feeling that, if a statistical association is confirmed by an animal experiment, definite proof of a cause and effect relationship in humans is established. It is important to realize that applications of the results of animal experiments to human situations are fraught with danger. If we are concerned with such disturbing influences as sampling and biological selection in studies of humans, we should be so much the more careful of basing conclusions on results of animal experiments. Confirmation by animal experimentation increases the biological reasonableness of a causal inference. It also provides an animal model by which possible biological mechanisms may be elucidated, thereby indicating how and where such mechanisms might be investigated in humans. But, in interpreting results from animal experiments, it is important to distinguish between definite proof and increased biological plausibility.

Nonbiological Considerations

Certain nonbiological considerations may influence an individual's attitude toward acceptance of a causal inference. These concern the decisions that are made relative to the course of action to be taken when an inference is accepted. They reflect the outlook, background, and administrative responsibilities of the individual. For example, a research scientist, without any direct responsibility for the health of a population, might require a very high degree of plausibility before accepting a causal inference and recommending definite administrative action. On the other hand, a health officer, directly responsible for the health of a population, may accept a lower degree of plausibility as sufficient to warrant preventive action. He may therefore accept a causal inference when he thinks that it has a good chance of being correct but before it is definitely proved.

Personnel Shortages in the Health Field and Working Patterns of Women

By WALTER L. JOHNSON, Ph.D.

ALTHOUGH it is well known that large numbers of women are attracted to the health and medical care field, the numerical extent of their employment and the trends toward their greater participation are not always recognized. In 1940, about 58 percent of all workers in the health field were women; by 1950, this proportion had increased to 63 percent (1a), distributed by occupation as follows:

| Occupation | Percent women |
|---------------------------|---------------|
| Professional worker..... | 63 |
| Service worker..... | 66 |
| Clerical worker..... | 91 |
| All other (residual)..... | 35 |

With the exception of the residual occupations, which constituted only about 9 percent of all workers in the health field, women predominated by a ratio of two or more to one.

A more detailed analysis of the professional group in the health field in 1950, including those in medical and other health services and in hospitals, reveals a similar pattern for specific professional occupations, except medicine and dentistry. The percentages of women in selected professions (1b, 2) are:

| Profession | Percent women |
|------------------------------------|---------------|
| Nurse, registered and student..... | 98 |
| Dietitian, nutritionist..... | 97 |
| Social worker..... | 81 |
| Medical technician..... | 60 |
| Physician..... | 6 |
| Dentist..... | 3 |

If physicians and dentists are excluded, about 9 out of 10 professional workers are women, a ratio which might surprise even those most familiar with the characteristics of health personnel.

This paper proposes to defend and emphasize the proposition that these facts identify a whole area of study which is relevant and significant to better understanding and control of personnel shortages in the health field today. Such an emphasis is needed for the reason that insufficient attention has been given to exploring the effect of this kind of sex ratio on the personnel turnover problem—either from the standpoint of measuring its relative influence on the entire personnel problem or of formulating possible courses of action in which this sex ratio is taken into account.

Of course, in a general way, it is widely recognized that the presence of women in significant numbers in any industry or occupation usually increases the magnitude of certain kinds of personnel problems over what they would be if high ratios for men prevailed. However, the application of this hypothesis in the collection of data to measure its effects or in the formulation of broadly conceived programs which cater

Dr. Johnson, at the time this analysis was made, was an instructor in sociology, department of environmental medicine and community health, College of Medicine at New York City, State University of New York. He is now co-director of research, Public Health Nursing Project, American Nurses' Foundation, Inc., New York, N. Y.

dividual's basic way of thinking about causal relationships.

We hope that this brief review of some of the methodological and inferential problems encountered in epidemiological studies will stimulate further discussion. There exists a compelling need for establishing some general principles which would provide a logical framework for future investigators.

CDC Course in Epidemiology for Nurses

A refresher course for nurses in communicable disease control will be given by the Communicable Disease Center, Public Health Service, Atlanta, Ga., from April 8 through April 26, 1957. The course is open to public health nurses and educational directors, industrial nurses, and instructors and consultants in nursing.

Designed to increase nurses' technical knowledge and skills in the prevention and control of communicable diseases, the course will stress epidemiological principles and techniques.

Supervised practice in the field may be arranged for a limited number of students after the termination of the course.

Applications must be filed with the Communicable Disease Center by March 10, 1957. Information and application forms may be obtained from the director of public health nursing in a State health department or from the Chief, Nursing Section, Epidemiology Branch, Communicable Disease Center, Public Health Service, 50 Seventh Street, NE., Atlanta, Ga.

force (table 2). In 1952, in an average month, for every 100 men entering the labor force 169 women entered, and for every 100 men leaving the labor force 170 women left. If the youngest and oldest age groups are excluded, since they are less stable in their labor force attachments, the differences between men and women become much more pronounced. For instance, in the age group 25-44, which constitutes nearly half the total and may be considered to be the backbone of the labor force, for every 100 men entering the labor force in an average month, about 500 women will enter, and for every 100 men withdrawing in the same period, about 500 women can be expected to withdraw.

The size of the differences in both of these measures is great enough to identify distinct variations between men and women in average individual work patterns. On the whole, working women do not have the close and sustained relationship to the labor force that men have, though of course the internal variation of individual cases around each hypothetical average is probably large enough so that there is a great deal of overlap in work patterns.

Factors Affecting Working Patterns of Women

The reasons women differ from men in their degree of attachment to the labor force are not difficult to find, and they have been recognized since women began to assume some importance

in the labor force. Women respond to the demands of the feminine role first and to occupational roles second. Hence, to a greater extent than is true of men, external and nonoccupational factors are of primary importance in modifying the occupational behavior of women. This more general point will be considered later but, before doing so, an attempt will be made to measure the strength of some of the specific factors which are associated with low rates of labor force participation by women.

Marriage

Marriage is the first factor which tends to detach women from gainful activity in the labor market. While there has been a steady and progressive increase of married women in the labor force in recent years, marriage still brings about a larger volume of withdrawals of women, age by age, from what it would have been if the women had remained single (*Id.*). Differences in labor force participation between single women and childless ever-married women are large in every age group, and it even appears that the differences increase with advancing age (see chart). Possibly 1 out of 3 or 4 women at work when they are single will cease to work when they marry or will withdraw from the labor force later.

There is added significance to these differences when it is seen that the proportion of all single women in the general population declines

to the needs of women has lagged. This is an omission which might be profitably explored in view of the likelihood that shortages of health personnel are likely to remain critical.

In presenting this point of view, no cure for these problems is offered. They have complex and ramifying roots, and long-range solutions will undoubtedly be difficult to achieve. On the other hand, even partial clues which may suggest operations for relieving some of the pressures on personnel administrators now and in the near future may not be wholly unwelcome, and it is within this more restricted framework that the following data are presented. It is also recognized that the data are not new but it is hoped that by presenting them in a systematic and moderately comprehensive way, they may shed new light on an old problem.

The specific aims of this paper are (a) to analyze certain differences in working activities and in strength of attachments to the labor force between men and women, (b) to review certain characteristics of women which affect the probabilities that they will or will not participate in the labor force, and (c) to suggest possible steps for mitigating personnel problems in the health field. Such broadly based factual data are a necessary first step in placing this facet of the problem in its proper context and, in lieu of particular data from the health field, will provide clues as to the specific influence of the sex ratio on the size of the personnel problem. A quantitative review of the data may also help the administrator to decide whether or not the effect of the sex ratio is sufficiently great to indicate further pursuit of the problem.

Sex Differences in Work Behavior

For many decades, the proportion of women in the labor force has risen continuously (3, 4). On the other hand, many differences in attitudes toward gainful work and in actual work behavior between men and women still prevail and will probably continue to prevail in the foreseeable future. An obvious example pertains to the important differences in classes of occupations and industries which attract women as compared with those which attract men (1b, 5). Another significant difference refers to the variations in stability and dura-

tion of employment. Both men and women move about a good deal within the labor force, that is, from job to job and from occupation to occupation (6-8), but their patterns of withdrawal from and reentry into the labor force itself are less similar. Women clearly differ from men in that they manifest a much larger volume of both withdrawal and reentry.

Monthly sample studies of the labor force, conducted by the Bureau of the Census, have presented two lines of evidence for measuring sex differences in participation in the labor force: (a) the work experience of the civilian noninstitutional population in the year preceding the January of enumeration insofar as these experiences could be constructed through retrospective methods and (b) monthly labor force turnover rates (9a, 9b).

First, with respect to annual work patterns, if the experience of any "normal" year is examined, that is, any year not marked by economic upheaval or war, it will be found that, (a) of all persons reporting any work experience for the year, a sizably larger proportion of women than of men will report part-time rather than full-time work during the year and (b) of those persons reporting any work, a sizably smaller proportion of women than of men will have reported working a full year (50-52 weeks). In 1954, for example, in the civilian noninstitutional population, over one-quarter of the women (27 percent) reporting work during the year worked at part-time jobs, whereas about one-tenth (11 percent) of the men employed worked at part-time jobs. Although among all women working during the year, over one-third (38 percent) reported that they worked for the full year, 66 percent or nearly two-thirds of the men stated that they had worked for the full year. These and other comparisons of annual work experience by age may be found in table 1.

Second, closely linked to these annual work patterns are the variations in labor force entry and withdrawal rates between men and women, and it is probable that differences in the volume of these movements largely account for the annual work experience patterns observed above. In any given year or month, a larger absolute number of women can be expected both to enter and to leave the labor

shows that there is a small but consistent decrease in the proportion of married women in the labor force with increasing numbers of children ever born to them, and these differences hold for all age groups.

In all instances, the rates of participation in the labor force by women with children are lower than for married women without children. The differences are most marked in the younger age groups, and here they are even greater than the differences between married women without children and single women. On the other hand, there is a good rise in the rate among the married women with children (except for those with children under 6 years of age), with the advancing age of the mother. This suggests that many women tend to reenter the labor force as their children become old enough not to require the kind of care necessary in the preschool and early school years. It may be this kind of movement which is partly responsible for the large number of additions of women to the labor force observed above. In any event, it is obvious that both marriage and parenthood are potent forces operating on the female labor market and that they bulk large in explaining the constant personnel turnover among women.

Also highlighted by these data is the quantitative importance of noneconomic and nonoccupational factors in the determination of when and how long women will be employed in the labor force.

Practical Implications

Differences in working patterns between men and women and the underlying attitudes and values which determine them are relevant facts to an industry such as the health field, which is heavily dependent on women for the delivery of services and the performance of necessary functions. Greater personnel problems can be expected, primarily for the reason that maintenance of the size of personnel is, potentially at least, a greater problem among women than among men. The working patterns of women and their possible role in contributing to the problems of personnel through attrition in this field should be given some consideration unless specifically disproved as not applicable to this

industry or to particular occupations within it. To give such recognition may help to identify areas where inordinate amounts of resources and energies are being applied to only small segments of the total personnel problem. An example might be the ease of an agency becoming concerned with working conditions and job satisfactions to the virtual exclusion of other considerations, on the assumption that these internal factors are exclusively related to holding employees to their jobs. It is clear that intrinsically, these are legitimate and significant organizational goals but if they are linked solely to solving personnel problems, it is not evident that they will be wholly successful. Particular agencies probably gain certain competitive advantages through such programs, thereby enabling them to attract personnel from other agencies. This, however, is analogous to robbing Peter to pay Paul, and the net effect toward the solution of the larger problem is zero.

Within broad limits, data of this sort suggest the systematic exploration of programs of action which aim more directly at utilizing to a greater extent some of the lost womanpower which attends the marginal status of women in the labor market. For example, greater flexibility in planning workloads and in making allowances for part-time work could be instituted in many instances. When compatible with organizational goals, conscious and deliberate attention to the needs of women, considered within their framework of reference and the competing demands on them, could conceivably be implemented to induce some women to maintain their attachments to the field or to return to it. Even a small measure of success along these lines would ease or mitigate a situation which is critical at the present time.

Another overlapping possibility suggested by this analysis is to take advantage of an ongoing trend, namely, the increase of married women with older children in the labor force, and to give greater consideration to recruitment from these ranks. It is perhaps unrealistic to assume that women of this age category could or should be persuaded to train for some occupation with formal requirements. On the other hand, within the field at the present time, there are certain on-the-job training experiences for some categories of personnel, and undoubtedly there

Table 2. Average monthly entries and withdrawals from the civilian labor force, by age and sex, United States, 1952

(Numbers in thousands)

| Age | Average civilian labor force | | Average monthly additions to the civilian labor force | | | Average monthly withdrawals from the civilian labor force | | |
|-------------|------------------------------|--------|---|--------|----------------------|---|--------|----------------------|
| | Male | Female | Male | Female | Female to male ratio | Male | Female | Female to male ratio |
| Total | 13,454 | 19,513 | 1,188 | 2,005 | 1.69 | 1,177 | 1,996 | 1.70 |
| 14-19 | 2,896 | 1,996 | 560 | 397 | .71 | 480 | 359 | .75 |

Source: Reference 9a.

precipitously within a short space of about 7 or 8 years. It may be estimated from census data (*1c*) that of a cohort of young women of the same age, about one-quarter will have married by age 19; by age 21, one-half will have married; by age 24, three-quarters will have married; and by age 26, about 83 percent will have married. For the specific age groups from 18 through 22, it can be estimated that 9 to 13 percent within each age group will marry each year. In view of the preceding data, the probabilities are high that a sizable minority of those who do marry will quit the labor market or will not enter it. Assuming that one-quarter of those who marry do leave the labor market, this would give a rate of attrition of about 2 or 3 percent per year of all women in each of these age groups.

Children

The second factor associated with widespread withdrawals of women from the labor force, which is more significant than the fact of marriage alone, is the arrival of children (*1d*). The effects of these responsibilities are particularly noticeable during the children's early formative years when the needs for continuous care and guidance are greatest. It is at this point that the lowest rates of participation by married women in the labor force are observed. Not more than about 9 to 13 percent of the married white women in any group with children

under 5 years of age were classified as in the labor force in 1950 (see chart). In addition to the age of the children, the number of children that mothers have to care for has some effect on labor force participation. The chart also

Percentage of white women in the labor force: single women; married women, by number of children ever born; and married women with children under 5 years of age, United States, 1950. (Source: Reference 1d.)

clean air

Samples of four papers presented at the 49th annual meeting of the Air Pollution Control Association, May 20-24, 1956, Buffalo, are the following condensations of papers by Dr. F. W. Bowditch, Dr. August T. Rossano, Dr. Charles R. Williams, and Benjamin Linsky, president of the association.

Organized in 1907, the Air Pollution Control Association is the only national association devoted solely to air pollution control. Its membership represents widely diversified interests of industry, science, education, government, and the public.

Technical committees of the organization develop standards and reports and initiate research for industry. APCA publications keep members informed of new equipment, surveys, and research.

The *Journal of the Air Pollution Control Association* is published four times a year. Abstracts of current literature are published monthly. The yearly proceedings contain all the papers presented at the annual meeting.

Copies of individual technical papers can be obtained from Harry C. Ballman, executive secretary, Air Pollution Control Association, 4400 Fifth Avenue, Pittsburgh 13, Pa.

The Louisville Study

PHR To meet the need for rubber products in World War II, the Federal Government embarked on an intensive program of synthetic rubber production. A large plant for production of chemical rubber was built in an industrially zoned area on the southwest side of Louisville, Ky. Within a short time a dense network of plants producing rubber or its components sprang up. The area appropriately became known as Rubbertown, and shortly thereafter residents of the West End, an adjacent residential area, began complaining of odors, dust, and eye irritation.

By August T. Rossano, Jr., Sc.D., director of field studies, Community Air Pollution Program, Robert A. Taft Sanitary Engineering Center, Public Health Service, Cincinnati.

This air pollution was generally attributed to operations in Rubbertown. Citizens' attempts at court action were unsuccessful.

History of Air Pollution Control

Louisville established a smoke commission which later became the Louisville Air Pollution Control Commission. After passage of a State enabling act, air pollution control became countywide with creation of the Jefferson County Air Pollution Control District in 1952.

Studies by the University of Louisville and the Battelle Memorial Institute attempted to determine the nature and source of air pollution in the West End. Their findings shed some light on the problem, but the results were not sufficiently conclusive to effect the desired abatement.

In July 1955, within a few days after Public Law 159 authorized the Public Health Service to establish a research and technical assistance

are many positions into which this age group could be fitted successfully. Moreover, there are many women, now inactive, who have been trained in skills in the health field. Nurses are an excellent example of such a group. It has been estimated that in 1951 the following proportions of nurses were active:

| <i>Age</i> | <i>Percent active</i> |
|------------------|-----------------------|
| Under 30..... | 53 |
| 30-39..... | 39 |
| 40-49..... | 35 |
| 50-59..... | 33 |
| 60 and over..... | 19 |

For all ages, about 45 percent of the nurses were estimated to be active (10). Until shown to be otherwise, it might be assumed that, given the appropriate conditions, many of these nurses could be induced to return to work in the health field. The same principle may also be applicable to other professional personnel.

Finally, one long-range solution which is suggested is the recruitment of men for ancillary positions in this field. The complexities of this approach are obvious, and in the short run chances of success are probably not great. This should not be allowed to obscure the possibility of change in the long run, however. It would seem that exploratory research and experiment in this area are indicated.

Summary

With the exception of physicians and dentists, the important professions and occupations in the health and medical care field are numerically dominated by women. This fact alone can be used to account for many of the personnel shortages in this field, when it is explicitly recognized that over a period of time the working patterns of women do not show the stability and continuity that are generally true for men. Because of marriage and childrearing, coupled with distinctive feminine attitudes toward work, large numbers of women tend to withdraw early from the labor force. This has the effect of creating many job vacancies where none would exist if the jobs were held by men and complicates the problem of personnel short-

ages already aggravated by general expansion in activity.

Certain practical steps may be taken to improve this situation. For example, greater attention to the needs and motivations of women and consideration of recruitment from the middle-aged group of women and from men are suggested.

Stations 1 and 3 are the upwind and downwind stations $3\frac{1}{2}$ miles from Rubbertown.

Station 5 is on a line between Rubbertown and station 1 and collects data to indicate the influence of distance from the source.

Stations 4 and 6, flanking station 5, increase the chances of collecting polluted air originating in Rubbertown and provide information on the concentration gradient across the polluted air stream under prevailing wind conditions.

Station 2, also on the $3\frac{1}{2}$ -mile arc, collects typical samples of urban air not directly influenced by Rubbertown pollution under normal conditions.

In addition at least one fully equipped mobile station, built into a small truck, will supplement the fixed stations.

Two conventional high-volume samplers, using glass-fiber or cellulose filter paper, operate alternately at each site on an 8-hour cycle and collect 3 samples daily from each. An automatic timer controls the operation at night.

One innovation is a specially designed standard shelter. Another is having the principal axis of the high-volume sampler on a vertical rather than horizontal plane, thus minimizing any preferential effects.

Modified filter-tape samplers permit analysis of particulate matter by flame photometry. Dustfall containers and adhesive surfaces are likewise provided. Collected material is subjected to special morphological examination.

The analysis of particulates collected by the high-volume samplers consists of determination of total loading and organic and inorganic fractions. Chlorides, sulfates, and nitrates are determined by wet chemical methods. Finally, an analysis for 19 cations is made by emission spectroscopy and flame photometry.

Nonspecific gas sampling on an intermittent basis includes evacuated glass, plastic, and stainless steel containers, and freeze-out traps that use liquid oxygen or nitrogen. Collected samples are analyzed in the mass spectrometer at the National Bureau of Standards. Specific gases are sampled by conventional scrubbers, absorbers, impingers, and evacuated flasks. Continuous gas sampling is presently confined to an SO_2 recorder, to be supplemented later by other SO_2 units and other automatic sampler-analyzer equipment. Under development are

Air sampling and meteorological stations, Louisville, Ky.

continuous gas-sampling techniques utilizing compression cylinders, resin and activated carbon adsorption, and gas chromatography.

Meteorological Network

Considerable effort is being devoted to operation of a comprehensive meteorological network, planned, serviced, and analyzed by Weather Bureau personnel assigned to the Sanitary Engineering Center of the Public Health Service and to Louisville. Two of the four main meteorological stations coincide with stations 1 and 3 of the sampling network.

The equipment at each station consists of a 61-foot aluminum and steel tower supporting a wind vane and anemometer wired at the tower base to continuous recorders. Each station has a recording hygrothermograph and wet-bulb and dry-bulb thermometers housed in standard shelters. Other hygrothermograph recorders are situated high on the south side and in the extreme northwest of the city.

Meteorological instruments installed on a television tower include a wind vane at 525 feet, thermohms at 50, 170, and 524 feet, and continuous recorders at the base. Tower instru-

program in air pollution, the Jefferson County Air Pollution Control District requested the Service to assist with a study of pollution in the West End. The interested agencies agreed to the Service's proposal for a joint Federal, State, and local study.

The study was formally initiated in January 1956. The schedule calls for 6 months of preparation for full-scale operation, 1 year of detailed study and observation, and 3 to 6 months to evaluate and report findings. The broad objectives are to augment existing knowledge of the nature, extent, and sources of the problem as a basis for rational control.

Memorandum of Agreement

The memorandum of agreement sets forth the conditions of the study. The Air Pollution Control District of Jefferson County, the Louisville and Jefferson County Board of Health, the Kentucky Department of Health, and the Community Air Pollution Program of the Public Health Service are the cooperating agencies.

A steering committee, consisting of a representative from each agency, assists the technical director in nontechnical matters. The director serves as executive secretary of the committee and presents monthly progress reports to it. The release of nontechnical information is by unanimous approval of the committee. Final reports will be issued jointly by the cooperating agencies.

The budget is approximately \$175,000 a year. The local contribution is largely in funds with which to procure additional personnel, equipment, supplies, and services. Industry has subscribed approximately half of the local funds. The Federal contribution is in technical services and equipment. Local and Federal contributions are approximately equal.

Preliminary Operations

Personnel were recruited through personal communication and advertisements in technical journals and local newspapers. Employment of the non-Federal staff is by contract between the individual and the county control district. Responsibility for recruitment and selection rests with the technical director.

His staff consists of an engineer in charge, who is responsible for administrative, statistical, engineering, chemical, and meteorological services, and 13 full-time employees, who include personnel from the local board of health, Air Pollution Control Board, and the United States Weather Bureau. In addition, private and governmental consultants participate in the study. The chemical laboratories are provided by the State health department.

Plan of Study

The first objective of the study is determination of the quality of the air in and around the West End by analyses for various particulate and gaseous pollutants and for variations and fluctuations in their concentrations. Time and space considerations include diurnal, seasonal, and long-range trends and patterns and comparisons of pollutant concentrations on the basis of their horizontal and vertical distribution.

The second major objective is a study of the relation to air quality of meteorological and micrometeorological factors.

In approaching these two objectives four basic principles were adopted as guides to air sampling and meteorological observations. They are:

A comprehensive network of fixed observation stations covering the area of interest.

Measurements on a simultaneous and continuous basis 24 hours every day including weekends and holidays.

Sampling periods as short as practicable to obtain data suitable for estimating diurnal patterns.

Thorough analysis of selected samples.

Air Sampling

The air sampling network (see chart) is laid out on concentric arcs 2 and $3\frac{1}{2}$ miles from Rubbertown. Most of the stations are between 10° and 50° azimuth to provide greater coverage for the West End area and take into account the prevailing wind direction from Rubbertown. Placing stations equally distant from the source eliminates the distance factor as a variable in comparisons of station results.

No community willingly accepts excessive visible automotive exhausts, undoubtedly because the point of exhaust is always less than 15 feet above the road. Usually, these objections are established in local or State traffic laws.

The Detroit Program

Detroit renewed its air pollution control program in 1947 with a new ordinance, new budget, and new staff. So comprehensive was the ordinance in its coverage that as early as 1948 violation notices were being written against smoky diesel trucks by air pollution inspectors using Ringelmann and Umbrascope scales.

The undesirable effects were primarily localized rather than areawide, in the categories of sky darkening, horizontal visibility interference, soiling of surfaces, and annoyance to human senses. The administrative methods used were politely worded violation notices, hearings on maintenance practices of truckers and bus operators to improve internal reporting and correction, and court enforcement.

Though these procedures were effective, difficulties were encountered. The air pollution inspectors, driving civilian cars, in civilian clothes, found it dangerous to stop smoky vehicles on expressways. The ordinance inadequately covered the heavy blue-white emissions from oil-burning jalopies and poorly fueled 2-cycle diesel engines. The automotive smoke problem became more apparent as other smoke problems were reduced.

Industry-City Effort

The Smoke Abatement Bureau of Detroit explored better ways of control. It was decided by the several departments involved that the motor vehicle code should be the basis for effective legal control and that the police would do the job of surveillance, patrolling, and field enforcement with assistance from the bureau.

Accordingly, an ordinance amending the code was drafted, cleared with the city, and introduced by the common council. It was read twice, ordered published, and laid on the table. Then things began to happen.

Engine makers, fleet operators, and bus and

Urban Effects

Linsky has classified eight undesirable community effects, areawide or localized, of air pollutants on level terrain, according to the following categories:

- Sky darkening.
 - Horizontal visibility interference.
 - Soiling of surfaces.
 - Vegetation damage.
 - Other property damage.
 - Interference with production or services.
 - Annoyance to human senses.
 - Direct damage to health.
-

truck makers and their organizations met with each other and with the smoke abatement bureau, police department, and corporation counsel. Truck fleet operators and engine salesmen explained to each other how excessive smoke could be avoided. The Automobile Manufacturers Association offered to work with the smoke abatement bureau to develop the best possible program in the hometown of the automobile industry.

The AMA's offer was accepted with a time limit for accomplishment. On its expiration a second time limit was set. Before it expired, the first portion of the project had been adopted by the council. How was this accomplished?

Steps Toward Agreement

First, the automotive industry, truckers, bus fleet operators, and city representatives talked out the problem. Together they observed cars, buses, and trucks at selected intersections. This established a uniform viewpoint and "equalized the ignorance." At this point the dramatic difference in the effects when different grades of diesel fuel oil were used in identical 2-cycle engine diesel buses belonging to different fleet operators was fully recognized.

The smoke abatement bureau assigned a supervising engineer to work with the AMA committee. Periodic meetings of the committee were held with legal advisers and the author to assure parallel viewpoints.

Meanwhile, a national bus company switched to use of a higher priced grade of diesel oil.

mentation will permit vertical soundings of the atmosphere for measuring its stability. Wire-sonde observations are made periodically with mobile meteorological equipment.

Source Inventory and Other Studies

The third phase is an inventory of air pollution sources in Rubbertown to learn the nature and rate of industrial discharges and develop a basis for regulatory measures. Preliminary studies are made of plant processes, materials, mechanical equipment, waste products, and points of emission. Detailed stack sampling operations are being carried out with the assistance of the Bureau of Mines and the Public Health Service to determine the amount and chemical composition of solid and gaseous wastes. In addition, size, shape, and surface area of emitted aerosols are determined. Tracer studies will determine the range and influence of selected point sources.

Another major phase is a survey of the nature and origin of objectionable odors in the West End. The procedure includes study of industrial operations and collection and cataloging of samples of odorous material. Staff personnel use odor reference kits during routine surveys and intense fumigations. The Sanitary Engineering Center is developing an olfactometer for quantification of odors.

A pilot study in the West End will determine the nature, extent, and relative frequency of intense local fumigations resulting in objectionable odors, excessive dust, or related discomforts. This undertaking depends largely on the cooperation of trained volunteer observers, who report monthly on their daily records of odor, dust, or irritating pollution incidents. This activity provides both a means for determining the type, location, and frequency of annoying fumigations and a way of alerting emergency crews to peak levels of pollution.

Early in the planning, a working relationship was established with the analytical statistics group of the Sanitary Engineering Center to handle the voluminous data anticipated. In addition to consultation in the design of the survey, the center assists project analysts in the reduction, analysis, and interpretation of data.

This air pollution investigation gives full cognizance to the importance of adequate public information. The public is given a clear understanding of the scope and general approach of the study, the participating organizations and staff, and the amount and variety of technical work required and is apprised of developments by successive news releases. The ultimate aim is favorable public opinion so that the findings and conclusions will be of maximum use.

Automotive Vehicle Fumes

PHR The automotive exhaust problem receiving the greatest attention since the tetraethyl lead scare of the 1920's relates to the areawide smog effects recognized frequently in Los Angeles and far less frequently in other metropolitan areas. The vegetation damage, rubber cracking, eye irritation, and visibility interference noted in Los Angeles are now generally attributed to invisible hydrocarbons and oxides of nitrogen in large part from automotive exhausts.

But the greatest private attention given air pollution from automotive exhausts relates to the localized effects that are recognized daily everywhere in the civilized world. The effects are annoyance to the senses because of odor, visibility interference from the plume, sky darkening by the plume, soiling of surfaces, and toxic effects of some of the gases in confined spaces and high traffic concentrations.

Automotive exhausts include, in addition to the invisible hydrocarbons and oxides of nitrogen, a variety of gases and solid and liquid particles such as invisible carbon monoxide, invisible aldehydes, other invisible nitrogen compounds, visible carbon, visible hydrocarbons, and other complex petrochemicals, invisible water vapor, visible water droplets, and metallic compounds.

By Benjamin Linsky, M.S.E., P.E., at the time of the conference, chief smoke inspector, Detroit Bureau of Smoke Inspection and Abatement, and now, control officer, San Francisco Bay Area Air Pollution Control District.

When Detroit sought some means of dealing with vehicles emitting unnecessary amounts of smoke, the AMA offered technical, legal, and engineering assistance. The association proposed a joint research program with the Detroit Smoke Abatement Bureau as a basis for planning satisfactory enforcement.

The subcommittee assigned the technical aspects of the study to a Special Group on Exhaust Smoke, composed of engineering representatives of the major automobile, truck, and engine manufacturers.

Unnecessary visible emissions from gasoline-powered vehicles are usually caused by excessive oil consumption resulting from worn piston rings, cylinder liners, and valve guides. Similar emissions from diesel engines generally result from overfueling that may be caused by incorrect injector adjustment or burned injector tips, restrictions in the inlet air system, substandard fuel, overloading, cold operation, or mechanical deterioration of the engine.

It was readily established that specific legal definitions, such as the length or duration of the emission, have been unsatisfactory in apprehending excessive "smokers." All vehicles do not have the same exhaust problems. Observations of exhaust lengths and duration depend on numerous factors.

Discussions with smoke abatement and police officials, supplemented by street observations, indicated the need to train enforcing officers in recognizing unsatisfactory smoke conditions.

As a first step, the special group produced a training film. Each participating company took color motion pictures of emissions from different types of vehicles against various backgrounds. Because of the difficulty in obtaining shots on city streets, running vehicles on company proving grounds simulated actual smoking conditions. Films best approaching typical conditions were combined in a preliminary film. The final professional version was based on the favorable response of city and industry officials to the preliminary film.

The next step is the development of portable guide materials for enforcement officers. Members of the special group are taking color still shots, which will be thoroughly reviewed with city representatives and user groups. A concurrent study is seeking means to reproduce the

pictures in realistic permanent form. The final result will be a kit of simplified charts for identifying grades of smoke emission from automobile exhaust.

Industry lawyers have worked closely with the smoke abatement bureau and the city corporation counsel in rephrasing sections of the ordinance that will complement the training materials. Concentrated, cooperative effort should accomplish the desired result with a minimum of inconvenience to the driving public.

Fluoride Air Pollution

Because sufficient concentrations of fluorides in the atmosphere may damage living matter, it is inevitable that some parts of the United States are concerned about preventing losses of fluorides in manufacturing processes. Industries processing rock phosphate, fluor spar, and other ores of fluorine compounds are the main producers. Industrial consumers contribute their share to air pollution by fluorides.

It is relatively simple to identify an industrial source of fluorides when there is a single producer in the locality, because of the readily detectable biological effects in the neighborhood. The nature of the environment in which the producer is located will determine, to a large degree, the extent of pollution.

Air pollution by fluorides does not mean that these pollutants are not controllable nor that economic loss is not preventable. Economic loss results only if there is sufficient contaminant to do damage and if there is anything to be damaged.

Increased production of fluorides by industries has accompanied increases in production of fluoride byproducts. Further, when such industries move into areas with little experience in control of air pollution, the degree of con-

By Charles R. Williams, Ph.D., associate professor of applied industrial hygiene, Harvard School of Public Health, and director, industrial hygiene services, Liberty Mutual Insurance Co., Boston.

The municipally owned system had done this several years earlier.

The first result was the AMA production of a training film to show the difference between necessary and unnecessary visible emissions.

The ordinance was rewritten by the engineers and legal specialists of the AMA and the city.

The film and its narrative were reviewed by the police department and the industry-city team. The rephrased ordinance was then discussed and agreed upon with one modification that grew out of the practical experience of the police traffic administrator.

The industry-city team then presented the film and the final ordinance to the common council. The council was told that a color-printed pocket guide on visible emissions was in preparation and that its use might justify a change in the ordinance within a year.

The ordinance became effective in April 1956 with the support of trucking, cartage, and automobile club representatives.

The industry-city team showed the film to 300 police traffic safety officers and discussed the ordinance.

The deputy superintendent of police instructed police to give warnings for 60 days and then issue violation tickets.

The police commissioner directed the police department to keep a running count of "smoking vehicle" violations.

Arrangements were made for the industry-city team to present the film and discuss the ordinance with traffic court judges and referees.

The Revised Ordinance

In the original ordinance, the responsibility for smoke violations was placed solely on the operator and did not cover the unattended vehicle with its engine running and smoking. It read:

"No motor vehicle operator shall run his motor with cintent open or make any other unnecessary sound disturbance or operate a vehicle emitting from any source an unreasonable quantity of smoke, noxious gases, or vapor."

In the new ordinance, the owner, lessor, and driver are responsible because real responsibility does not always rest with the driver. Prob-

ably he should be solely responsible only when his "heavy foot" or "lazy gear shift hand" allows a diesel engine to lug at low engine speed. The new ordinance covers moving or stationary vehicles and adds the words "excessive," "unnecessary," and "obnoxious" to "unreasonable" in the original. It reads:

"No person, firm, or corporation shall operate or cause to be operated upon any street, highway, or other public place a motor vehicle, while stationary or moving, which emits from any source any unreasonable, excessive, or unnecessary smoke, obnoxious or noxious gases, or vapor."

"Unnecessary" was inserted to cover the heavy foot of the jackrabbit driver of a diesel vehicle, the use of a grade of diesel oil other than that specified by the engine maker, worn piston rings on a gasoline engine, and similar conditions.

"Excessive" was inserted primarily to cover the situation where a diesel engine is too low powered to handle the load with the gearset provided, with a resulting low engine speed, high torque, and shortage of combustion air.

"Obnoxious" was added to acknowledge that the odor of exhaust gases may be controlled through proper equipment design. Engineering advances make this practical, especially for 2-cycle diesel engines and the larger gasoline engines.

Automotive Industry Effort

Industry research by automotive manufacturers over the past years has helped reduce smoke emission from new motor vehicles. In recent years their interest has been formalized in the establishment of the Vehicle Combustion Products Subcommittee of the Automobile Manufacturers Association. This group has engaged in extensive cooperative research on exhaust emissions.

By F. H. Bowditch, Ph.D., chairman of the Special Group on Exhaust Smoke of the Automobile Manufacturers Association and senior research engineer at the General Motors Technical Center, Detroit.

size of the furnaces, on the operating procedures, and on the attempts to control the effluent.

One major approach is the installation of sprays and roof monitors to trap fluorides, but this solution has been unsatisfactory.

A second method is to provide local exhaust ventilation on each furnace and to remove the fluorides by passing the exhausted air through scrubbing towers. The effectiveness of recovery depends primarily on the kind of hood, the volume of air, and the type of scrubber.

Scrubbing systems are costly because of the large volume of air exhausted from large numbers of furnaces. In some plants, $2\frac{1}{2}$ to 3 million cubic feet of air a minute are exhausted and scrubbed.

Aluminum production depends primarily on availability of ore and cost of power. The plants of six producers are located in Arkansas, Alabama, Louisiana, Montana, North Carolina, New York, Oregon, Texas, and Washington.

To judge by damage claims resulting from injury to cattle and vegetation in the Pacific northwest, it is obvious that aluminum reduction plants cannot operate without controlling the fluoride effluent.

Evaluating Pollution Levels

It is almost impossible to set permissible levels for the amount of fluoride effluent. The severity of the problem depends on the amount of emission and its distribution. Distribution is affected by climate, wind direction, and terrain. Time is a factor because gaseous fluo-

rides may be retained and built up in vegetation.

Continuous sampling of vegetation is the most satisfactory way of evaluating fluoride pollution of the air. A grid system and periodic samples of different kinds of vegetation collected during the growing season best measure the effectiveness of control.

There are few valid criteria for fluorides in vegetation because of two complex factors. One relates to the amount of fluoride that will cause plant damage; the other to the amount that will produce injury in animals which consume the vegetation.

The levels that will damage vegetation vary with species over an extreme range. Fruit trees and some types of flowers are particularly susceptible to injury at low concentrations. Levels in grasses and animal feed that will injure cattle also vary with the condition of the cattle, fluoride intake from water and other sources, and time of exposure.

Extensive fluoride damage has cost industry millions of dollars. In many instances, the cost of claims has been staggering.

To avoid further economic loss, the dissemination of fluorides must be substantially reduced. Ventilation and collection should be installed when a plant is constructed. Vegetation levels should be kept below 30 p.p.m. to prevent damage to cattle.

With the extensive data available, it is obvious that no plant emitting large amounts of fluoride can afford to neglect the engineering necessary to atmospheric safety. The possibility that fluoride recovery may prove profitable, also, is only an added incentive.

Fluoridation Progress

Communities with a combined population of 6 million started fluoridating their water supplies in the first 9 months of 1956. The average annual increase for the past 5 years has been 4 million.

The latest tabulation by the Public Health Service shows that fluoridated drinking water is now supplied to one-fourth of the people using public water supplies. About 1,400 cities and towns with a population of over 30 million people were using fluoridated water at the end of September.

tamination tends to run ahead of control measures.

Phosphate Rock

Phosphate rock is used primarily for production of superphosphates (fertilizers), food and medicinal phosphates, elemental phosphorus, phosphoric acid, ferrophosphorus, and stock and poultry feed. It is also applied directly to the soil as fertilizer.

In Florida and the four western States of Idaho, Montana, Utah, and Wyoming, production has more than doubled since the war. In Tennessee, it has remained relatively stable. United States production increased from 5,399,739 long tons in 1945 to 12,031,213 in 1952.

In general, superphosphates are processed near the source of the ore, but availability and cost of power influences the location for manufacture of elemental phosphorus. Since Florida lacks sufficient power for phosphorus production, it uses most of its rock phosphate for fertilizer. Tennessee and the western States predominate in phosphorus production because of abundant power.

Rock phosphate, if it is high-grade ore, contains 2 to 3 percent fluorine. Fluorine is present in a fixed ratio to phosphorus, roughly 25 tons F in every 1,000 tons of rock processed. Wherever the rock is so processed that fluorophosphate is broken down, large quantities of fluorides can be released.

For every ton of rock processed, 40 to 60 lb. F may be released. A plant processing 1,000 tons a day can produce serious pollution if uncontrolled.

In the production of elemental phosphorus, the fluoride may be released in several processing steps. Because of the complexity of the operation, fluoride balance studies are needed to determine where losses in production actually occur. From an economic standpoint, it is wise to apply control measures only where they are really needed.

Some fluoride loss occurs in calcining or sintering the ore, depending on the temperatures used. Significant loss may occur in the electric furnaces, as fluorides escape into plant air and to the outdoor atmosphere. Other loss is in the off-gas, which in burning releases flu-

oride to the atmosphere. Substantial amounts of fluoride may be trapped in furnace slag and released as the slag cools.

In the production of superphosphate, the rock is treated with sulfuric acid with a resulting release of hydrogen fluoride and silicon tetrafluoride. The nature of the operation calls for its location in agricultural areas. Large tonnages of ore are handled, and, thus, large quantities of gaseous fluoride are released.

In the production of concentrated superphosphate, a new development in fertilizer manufacture, the release of fluorides is even greater. In some areas, damage has progressed from borderline to definite. This fertilizer is made by producing phosphoric acid from phosphate rock and treating additional rock with the acid.

Control efforts in each of two small areas, one in Florida and one in Tennessee, have been complicated by fluoride emissions from 10 to 12 plants producing superphosphate, phosphoric acid, animal and poultry feeds, and elemental phosphorus. With so many plants and their wide variations in manufacture, it is almost impossible to assess the blame for damage. Since the ultimate criterion is the total amount of fluoride emitted in an area, the permissible effluent from each plant must be reduced substantially.

Major Industrial Users

Fluorides used in the production of steel and aluminum are another large-scale source of pollution.

Though it is difficult to assess the proportions of fluorides released to the air, the steel industry is a major user of fluorspar, primarily as a flux in the manufacture of basic open hearth and basic electric steel. The industry used 53 percent of the fluorspar and 34 percent of the hydrofluoric acid consumed in 1952.

In the production of aluminum metal, the refined ore (alumina) is mixed with fluorides in electrolytic furnaces. The fluorides act as a flux and are released to the atmosphere as a result of decomposition under high temperature. They are carried upward by convection and, in the absence of local exhaust, are generally released through roof louvers. The amount escaping depends on the number and

Durability Tests Of Stainless Steel Hospital Utensils

By ARNOLD H. DODGE, B.S.

THE CIVILIAN HEALTH Requirements Program of the Public Health Service is seeking to determine whether hospital items made from non-nickel chrome steel (known usually as type 430 or type 17, containing about 17 percent chromium) are as durable as items made of the conventional chrome nickel stainless steel. Should the lack of nickel sufficiently impair the wearability of such items, it would be poor economy to deprive these items of that metal. The amount of nickel used in the hospital items is trivial when compared with total consumption. On the other hand, there is no point in continuing to use a strategic metal if such use is demonstrably extravagant and unnecessary. To determine whether or not nickel should be allocated to hospital items under a nickel control plan, it seemed desirable to obtain durability test information.

Stainless steel is essentially an alloy of iron and chromium. Nickel and other elements are often added to improve workability and to add corrosion resistance that will withstand special or unusually severe conditions.

For more than 20 years, certain articles of operating room furniture and hospital utensils in common use have been fabricated from a chrome nickel stainless steel, known usually as type 302 or 18-8 and containing about 18 percent chromium and 8 percent nickel. There has been a chronic countrywide shortage of nickel for most of this period. During World War II and the Korean emergency, supplies of nickel fell far short of demand, and controls were established to cover essential mili-

tary needs. Nickel has recently become more important to the national defense because of the wide application of this metal in the field of atomic energy and specialized military activities. Logically, it is mandatory that the use of nickel be restricted to essential commodities during periods of war. Whenever possible, however, nickel-free alternates to the products affected by conservation orders should still be useful for economic reasons.

Hospital Utensils

In February 1952, during the emergency in Korea, a meeting of an industry advisory committee of utensil manufacturers was held at the request of the National Production Authority (now the Business and Defense Services Administration). The agenda included, among other things, industry requests for assurance of a continued supply of chrome nickel stainless steel for the manufacture of hospital utensils and a discussion of the necessity for chrome nickel stainless steel in this class of items. If type 430 stainless steel is used exclusively, an estimated 10,000 pounds of nickel could be diverted annually to other purposes. Since no accurate or detailed information was known to be available about the durability of non-nickel stainless steel utensils, it was agreed to study selected utensils in use. The control authorities agreed that while the study proceeded manufacturers would continue to receive allocations of nickel-bearing stainless steel. Industry representatives offered to provide nickel-free utensils for the study. The Public Health Service agreed to oversee and arrange for tests in a hospital of six of each of the following utensils: bedpans, urinals, kickbuckets, and catheter trays with covers. Three of each were type 430 and three of each were type 302.

Through the cooperation of the American Hospital Association, arrangements were made to place the utensils in regular service at the Wesley Memorial Hospital in Chicago in September 1952. Basic instructions called for all test items to be kept in continual routine service and to be treated in the usual manner. Only supervisory personnel were aware of the test.

After 1 year of use, the utensils were forwarded to the office of Civilian Health Re-

Mr. Dodge is a senior pharmacist assigned to the Civilian Health Requirements Program, Office of the Surgeon General, Public Health Service. His paper is an interim report on a long-term study.

Device for Standardizing X-ray Techniques

A large plastic stepped wedge, which facilitates the coordination of research facilities, roentgen film, equipment and technical procedures, providing a high degree of uniformity in results, is being used by the Medical Investigations Branch, National Institute of Dental Research, Public Health Service. This is part of a broad-spectrum research program which embodies extensive roentgen procedures in keeping with the need for long-range human population group studies, correlating systematic conditions with dental problems.

A salient aspect of these studies is the repeated roentgenographic evaluation of individuals and population groups over a span of years. To assure uniform and valid results, roentgen procedures have been standardized as much as possible within the realm of practicality. This has been achieved to a fair degree with the help of Robert Morrison, medical division, and Dr. Herman E. Seeman, research laboratories of the Eastman Kodak Company, Rochester, N. Y.

Dr. Seeman, long interested in this type of problem, developed the plastic stepped wedge which meets the unique requirements of the study series.

The dimensions of the wedge are such that its thinner sections require the same exposure as thin patients and the thicker portions correspond similarly to heavy patients. In use, it is radiographed several times with a variety of techniques representative of those used for the normal range in patient size. The radiographs and data are filed for later reference. At some prescribed time, say a year later, the wedge is again radiographed, using the same nominal techniques. If the radiographs match those made the year before, it may be concluded that no significant change has occurred

in the equipment or materials used. If the radiographs do not match, the techniques or processing are modified until a match is obtained or film interpretations are made on the basis of the variation. In this manner, it is possible to maintain a given diagnostic film quality even with a variety of changes.

This must not be considered the final answer to highly technical or scientific activities requiring carefully standardized techniques but constitutes a tool, particularly adaptable to field use, that affords a large degree of uniformity in procedure and results. It is obvious that the stepped wedge should be composed of a substance similar to bone and soft tissue in terms of radiographic qualities. However, the more it approaches the realistic, the more complicated is its application to the problem. It is better to have a simple, practical procedure with some assurance that it will be applied than a

more refined one which will be neglected because of the need for interpreting exact measurements.

The device permits a practical degree of standardization for studies, film, developer, equipment, or technique changes. It serves to check on radiographic quality, demonstrating gradual deviation that might accrue through virtue of technique, processing, or photographic deterioration. More finite comparisons are permitted through the use of a densitometer, plotting a series of curves in relation to the respective circumstances.

An epidemiological roentgen study in itself is unique, and the standardized X-ray techniques, utilized to facilitate the studies, constitute an unusual approach to clinical research. The device itself is a practical approach to a number of common problems routinely encountered in radiographic installations where volume warrants its use.

quirements. With the exception of one type 430 urinal, all utensils were accounted for. These were inspected by representatives of interested Government agencies, including stainless steel and corrosion experts from the National Bureau of Standards, Armed Services Medical Procurement Agency, and the Business and Defense Services Administration of the Department of Commerce.

After a review of the findings, it was decided at a subsequent industry advisory committee meeting that the utensils should be tested further and that the testing institution should, preferably, be near the seashore so the effects of salt air on the utensils could be studied. The Department of Defense arranged for a controlled test at the Key West Naval Hospital in Florida.

The second test was completed and the utensils were returned to Washington for inspection by the same agencies. (One urinal and one kickbucket, both type 430, were misplaced and not returned from Key West). Results of the two tests appear on facing page.

Operating Room Furniture

In addition to the control on the use of nickel in utensils, the National Production Administration, early in 1951, had issued a restrictive order (NPA Order M-80) which prohibited the use of nickel steel in the manufacture of operating room furniture.

By a fortunate coincidence, purchase orders for equipment for the Clinical Center at the Public Health Service National Institutes of Health, then under construction, were being compiled. With this opportunity to test operating room furniture made from type 430 stainless steel, specifications were modified on a selected list of items. The following type 430 stainless steel items containing no nickel were among those obtained from the manufacturer:

- 1 linen hamper.
- 3 stands, irrigator (not placed in service).
- 1 stand, solution, single, Baker model.
- 1 stand, solution, double, Snyder model.
- 1 table, major operating pedestal, large.
- 2 stands, instrument, Mayo.
- 1 stool, anesthetist's, Bryson model.
- 2 stools, foot, 10' x 14' x 8'.
- 2 stools, revolving.

1 stool, foot, 12' x 30' x 4'.

2 tables, instrument, curved, 12' x 60' x 33' (not placed in service).

1 table, utility, 16' x 20' x 33'.

1 table, utility, 16' x 20' x 30' (not placed in service).

The operating room furniture serving as controls has not been listed above because adequate control was afforded by the normal course of simultaneous purchases of type 302 duplicate chrome nickel items for the other Clinical Center operating rooms. The operating room furniture was placed in general service in July 1953 at the Clinical Center. After 1 year of use it was inspected by the Sanitary Engineering Branch of the Division of Research Services, National Institutes of Health, and was then returned to routine service for a second year. The operating room furniture was inspected at the end of the second year by the National Bureau of Standards as well as the Sanitary Engineering Branch.

Detailed reports on individual items of operating room furniture for the first year were not received. However, all furniture pieces fabricated from type 430 stainless steel compared favorably with the type 302 items, except for surface scratches. Both types of furniture were kept in continual and equal service, and all surfaces were kept scrupulously clean. No significant signs of rust, pitting, or staining were reported at the end of 1 year. Detailed results of the second year tests follow.

Continuation of Tests

Upon completion of the second year of testing and inspection, the interested agencies agreed that periodical examination of the equipment should be continued indefinitely. Preferably, this additional testing would continue until failure of each item.

In addition to the continuation of the tests at the Clinical Center, the Bureau of Medical Services of the Public Health Service provided another site for the utensil testing, the Public Health Service Hospital in Baltimore, Md. By the use of a "quarterly inventory-annual report" system, followup information is expected to be current. Due to the long period which may be required, each utensil was engraved "on

Hospital Utensils

FIRST YEAR INSPECTION RESULTS

| Item | Type 302 (8 percent nickel) | Type 430 (no nickel) |
|--|--|---|
| Bedpans | Few scattered pits on inside bottom; slight discoloration; some corrosion and rust at weld line. | Many small scattered pits on inside; rust and pits at weld line; some discoloration. |
| Kickbuckets | Some discoloration; few light rust spots and pits on inside. | Moderate discoloration; rust spots and few deep pits on inside. |
| Urinals | Inside coated with deposit; spot welds on handle show rust; some rust and pits on inside walls and bottom inside; some staining. | Considerable rust inside at welds (handle); moderate staining or rust in neck and some pitting inside bottom. One had fabrication tear at pour lip. |
| Instrument trays with covers (8" x 2½" x 1½"). | Except for slight dulling and baked-on deposits of previous contents, no defects. | Same as type 302 plus slight rust on one cover inside. |

CONCLUSIONS: It was the consensus of those examining the utensils that there was a definite need for improved cleaning techniques. It was their opinion that proper cleaning should improve corrosion resistance of both types of stainless steel. Type 302 showed superiority in corrosion resistance. However, the usefulness of

type 430 utensils was not diminished because of the defects noted and there was no conclusive indication of early failure. One year of test proved insufficient to determine durability of type 430 stainless steel hospital utensils.

SECOND YEAR INSPECTION RESULTS

| | | |
|--|--|--|
| Bedpans | Few light rust stains on outside; some rust along weld on inside, also occasional rust spots on inside bottom and rolled head (hem). | Few rust spots and pits on outside and along weld; numerous rust spots mainly on inside weld seam and head. Scattered tiny pits on bottom. |
| Kickbuckets | Occasional discolored area on outside; few scattered rust stains, discolored areas, and etched spots on inside. One had several dark etched areas. Rust at a bail ear was observed on one. | Mottled and discolored on outside. One showed rust staining on outside bottom and mottled rust stains on a bail ear. One bucket, showing evidence of improper use, had four severe etched areas on curve of inside bottom; one area was perforated to the outside, making the bucket useless. Another bucket showed heavy etching on inside, with extensive discoloration to bottom third of bucket. Many etched and red rust spots and tiny pits were noted in discolored area. |
| Urinals | Occasional red rust stains at edge of rolled rim; superficial corrosion at handle welds; inside heavily discolored and coated with deposit; scattered rust spots on inside. | Rust on rolled rim; occasional rust spot and pits on outside. One had fabrication tear on pour lip. Heavy deposit on inside with discoloration pitting and rust spots on inside weld area. |
| Instrument trays with covers (8" x 2½" x 1½"). | Slight dulling of sheen on inside. | Occasional tiny pit and rust spot on inside. |

CONCLUSIONS: After examination by essentially the same group who inspected the items 1 year earlier, it was felt that only moderate changes in type 302 chrome-nickel stainless steel were noted. Aside from the perforated kickbucket, serviceability of utensils was not significantly diminished by the use of type 430 non-nickel stainless steel. It was again evident that proper

or complete cleaning was not accomplished and that this point must be emphasized to obtain the best service from all stainless steel utensils in hospitals. It was the opinion of the inspecting group that type 302 stainless steel showed superiority over the type 430, but additional testing should be pursued before final judgment.

The American Cancer Society

By THEODORE ADAMS

IT was in May 1913 that a small group of forward-looking physicians and laymen in New York City took the decisive step of forming the parent national organization of the American Cancer Society. They named it the American Society for the Control of Cancer. The \$10,000 contributed the first year was used to publish a pamphlet and promote discussions in women's clubs of a taboo subject—cancer.

In contrast to that small beginning, the Nation in 1956 contributed \$27,000,000 to the American Cancer Society's coordinated, countrywide program of public and professional education about cancer, service to patients, and scientific research into the cause and cure of this disease.

The American Cancer Society is a voluntary organization of people united to speed the conquest of cancer. It is composed of 60 chartered divisions serving the 48 States and Alaska through 2,788 organized units and more than a million volunteers. The divisions and units operate under volunteer directors, or governing committees, composed of lay and professional people who formulate policies and program objectives within the framework of national and divisional policies. Represented on the national board of the society are all areas of the country and business, industry, law, science, medicine, and communications. The society reports annually to the contributing public about funds collected and expenditures made. The president of the American Cancer Society is Dr. David A. Wood, director of the Cancer Research Institute and professor of pathology,

University of California. Chairman of the board is Walter J. Kohler, former Governor of Wisconsin.

Research

Research takes a big chunk out of the annual budget. This is natural, for the society believes, along with informed minds everywhere, that research is the key to the conquest of cancer. As a result, each year 25 percent of all funds received by the society have gone into its national research program. Since 1945, when this program was launched, almost \$50 million has been invested in grants for cancer research in the Nation's leading hospitals, universities, and other laboratories. Today, the work of a thousand senior scientists, assisted by some 3,000 younger workers, is backed by society funds. The investment has paid off by advancing fundamental knowledge of the life and growth processes, improved radiation and surgical techniques, and the development of lifesaving and pain-easing drugs, some of which can bring about temporary control of malignant growths.

The year 1956 also saw a dramatic reappraisal of the research program to speed developments and save lives. Approved by the board of directors were the basic recommendations of the society's Ad Hoc Research Policy Survey Committee for four types of grants for the support of research and four for the training and support of investigators. The philosophy behind the recommendations is embodied in the committee's report, which stresses continuity of research "to assure that the scientists now being trained are able to realize their maximum potential for fully imaginative and productive research, and to make a career in cancer research

Mr. Adams is director of the publications section of the American Cancer Society.

Operating Room Furniture

SECOND YEAR INSPECTION RESULTS

| Item | Type 302 (8 percent nickel) | Type 430 (no nickel) |
|--------------------------------|---|--|
| Utility tables, | A few scratches on surfaces. | Top scratched and discolored. Discoloration but no rust at welds. |
| Stools, revolving | No indications of rust. | Slight rust where ring welded to legs on one. |
| Operating tables | do | No indications of rust. |
| Solution basin stands, single | do | Some discoloration at welds but no rust stains. |
| Solution basin stands, double. | do | No indications of rust. |
| Stands, Mayo type | do | Do. |
| Stools, dentist's | do | Do. |
| Stools, foot | Slight rust stains at junction of lines with seat and at welds on legs. | Definite rust at junction of lines with seat and at welds on legs. |
| Linum hamper racks | Few scratches; clean welds. | No indications of rust; clean welds. |

CONCLUSIONS: The summary judgment reached by those examining the items was that type 302 articles are in slightly better condition than type 430. The difference, however, is not significant at this time. The evidence of excellent cleaning was apparent for all items

inspected. An interim judgment would suggest that hospital operating room furniture fabricated from type 430 chrome stainless steel would be sufficiently durable to serve as a satisfactory alternate for type 302 chrome nickel stainless steel.

test" and assigned an arbitrary number for positive long-term identification. Information as to failure or significant signs of early failure will be forwarded to mobilization planning agencies at appropriate intervals.

The marked evidence that routine cleaning methods of the utensils was inadequate obviously indicates that more information on the care of stainless steel should be disseminated. In this regard, through the efforts of the National Research Council and of the American Iron and Steel Institute, the preparation of a comprehensive booklet covering the care of stainless steel is being considered. Hospital administrators and others concerned with extending the life and maintaining the appearance of

stainless steel utensils and fixtures will find such a booklet very practical.

Summary

After 2 years of service testing of hospital utensils and operating room furniture, there is evidence that nickel-bearing stainless steel, with its corrosion resistance characteristics, is superior to non-nickel stainless steel. The margin of superiority noted, however, was not conspicuous in the furniture. With the exception of one kickbucket, deterioration was generally not severe or of a nature to destroy the usefulness of the article. Only minor instances of deterioration were observed in the non-nickel stainless steel operating room furniture.

Professional Nurse Traineeship Program

In a new program enacted by Congress on July 23, 1956, the Public Health Service is providing traineeships to assist graduate nurses in furthering their professional education.

For the academic year 1956-57, 553 traineeships totaling nearly \$2 million have been awarded under the new law (P. L. 911, Title II) to 56 schools of nursing and schools of public health throughout the United States and in Puerto Rico.

Mary O. Jenney, a Public Health Service officer since 1942, is in charge of the new program. She had been with the Division of Hospitals since 1947.

standing committee of the national board, of a Public Education Committee under the chairmanship of Dr. Frank M. Stanton, president of the Columbia Broadcasting System.

On the State and local level, the society's divisions and units work in cooperation with other national organizations, thereby reinforcing divisional public education activities. In 1955 the American Cancer Society worked with the American Public Health Association, the Industrial Medical Association, the National Science Teachers Association, the National Conference for Cooperation in Health Education, AFL-CIO, the Women's Auxiliary of the American Medical Association, the General Federation of Women's Clubs, and many others.

A recent public opinion poll has shown excellent results from the American Cancer Society's education program, although groups of low income and of lesser educational advantage still need much attention.

A major objective of the society's professional education program is to alert physicians everywhere to the possibility of cancer in all patients and to provide them with information that will aid its detection in an early, curable stage. A second objective is to improve the means for the diagnosis and effective treatment of cancer through special training given individual physicians. Closely related are the society's medical service activities, which provide needed medical laboratory services, equipment, and forms of organization designed to assure accurate case records and consultation between physicians on treatment and followup procedures. Close cooperation with State and local medical societies and hospitals is the rule. Grants are made to institutions approved for postgraduate training by the American Medical Association's Council on Medical Education and Hospitals, the institutions themselves designating the individual fellows. Thus, physicians completing their fellowships enter or return to practice with invaluable direct experience in basic medical problems of cancer.

Since the start of this program in 1948, a total of 864 fellowships has been awarded to 56 institutions. In addition, since 1950 grants of the society have contributed each year to the advanced training in cancer for physicians at the Memorial Cancer Center, New York City,

where 122 fellowships were awarded for the 1955-56 academic year alone. Since its inception in 1948 a total of \$2,493,690 has been devoted to this program.

The society publishes two bimonthly periodicals: *Cancer*, a scholarly journal for the clinical investigator, and *CA: A Bulletin of Cancer Progress* for the practitioner. The society's medical library prepares special bibliographies on cancer and issues to medical schools and libraries *Cancer Current Literature*, a monthly index. Other activities of the society for the benefit of the medical profession include a cancer monograph series, demonstration slides, medical exhibits, and special films.

Service

Units in most divisions of the society are organized on a county basis. Since much of the society's work is medical in character, local medical societies, hospitals, and departments of health are broadly represented on unit boards. In addition to basic community education and campaign activities, many of the units participate in hospital diagnostic and consultative services, cancer registries, cancer detection programs, lung cancer screening programs, nursing service, medical social work, and transportation of patients.

In 1955, 2,590 cancer information centers for the public were maintained by units, 410 of them on a full-time basis. Financial support was given to 387 hospital diagnostic and treatment services. Subsidies to visiting nurses' organizations made possible 202,103 visits to needy cancer patients.

Approximately one-third of the society's volunteers are engaged in service activities for cancer patients and their families. Almost 200,000 volunteers made 19,110,380 cancer dressings, which were distributed free to cancer patients. Unit loan closets, equipped with sick-room necessities, were supplied free to 20,754 patients.

Liaison With NCI

The society maintains continuous liaison with the National Cancer Institute of the Public Health Service. Working together, the two

so attractive as to lure the more capable and ingenious of the potential candidates."

Culminating a year's study by top-level scientists and administrators, the action was designed to meet more adequately the needs of the present advanced status of research by:

1. Establishing new types of research grants to individuals and institutions that will permit longer range planning and more flexible use of funds so that promising new leads may be pursued more rapidly.

2. Assuring more adequate manpower for cancer research by expanding the program of training to young scientists and establishing long-term faculty level positions in universities to attract more scientists to the field of medical research and keep them in it.

3. Coordinating under one Scientific Advisory Council the society's entire research program, which had become divided into a number of more or less independent efforts during the organization's rapid 10-year growth.

Following up these developments, the society, in August 1956, named 15 of the Nation's leading scientists and research administrators as members of the newly formed Scientific Advisory Council of the American Cancer Society. The appointments were announced by Governor Kohler, who said, "We have asked these scientists to serve as the primary guiding force in blueprinting the direction that our research program will take. They have a tremendous responsibility, but also the challenging opportunity to devote their talents and vast experience towards the ultimate solution of the cancer problem. The board of directors is gratified that some of the best scientific brains in the country have been assembled for this all-out attempt to discover the causes of cancer and to evolve better methods of control and cure."

Action by the American Cancer Society board directs that the new Scientific Advisory Council examine continuously progress in cancer research. The council will survey what is being done by both governmental and privately financed groups and will determine which are the most promising of the unmet needs. Recommendations will then be made for appropriation of funds in whatever categories are indicated. The council will review the recommendations

ACS Scientific Advisory Council

The American Cancer Society Scientific Advisory Council consists of the following:

Dr. George W. Beadle, chairman, California Institute of Technology, Pasadena; Dr. Walter J. Burdette, St. Louis University, St. Louis, Mo.; Dr. Philip P. Cohen, University of Wisconsin, Madison; Dr. Howard J. Curtis, Brookhaven National Laboratory, Upton, Long Island, N. Y.; Dr. Harold F. Dorn, Public Health Service, Bethesda, Md.; Dr. Thomas Francis, Jr., University of Michigan, Ann Arbor.

Dr. Alfred Gellhorn, Columbia University, New York City; Dr. Eugene P. Pendergrass, University of Pennsylvania, Philadelphia; John M. Russell, the John and Mary R. Markle Foundation, New York City; Dr. George Sayers, Western Reserve University, Cleveland, Ohio; Dr. Howard E. Skipper, Southern Research Institute, Birmingham, Ala.; Dr. Edward L. Tatum, Stanford University, Palo Alto, Calif.; Dr. Arnold D. Welch, Yale University, New Haven, Conn.; Dr. Milton C. Winternitz, National Research Council (retired), Washington, D. C.; and Dr. Gordon Zubrod, Public Health Service, Bethesda, Md.

of special scientific advisory committees dealing with specific areas of responsibility such as the cause, pathogenesis and treatment of cancer, institutional research grants, and personnel for research. Special areas will also be covered. For example, continuation of the existing Research Advisory Committee on Lung Cancer was authorized.

Education

The public education program of the national society is enhanced by year-round programs in the divisions. The program is concerned with audiences and is projected under formal headings of mass media, employee education, club and organization, school and college, and neighborhood educational programs. In 1955 more than 60 million copies of the society's leaflet, "Seven Danger Signals," were distributed. The same year the society's work in public education was strengthened by the establishment, as a

Syphilis Morbidity Reporting by Private Physicians

By EUGENE E. TAYLOR, M.D., M.P.H., and JOHN J. WRIGHT, M.D., M.P.H.

THE PROCESS by which private physicians report cases of communicable disease has often been a source of concern to public health officials. These officials have feared that reports were incomplete and were an unreliable basis for attempts to measure a communicable disease problem.

Syphilis case reporting presents certain distinctive difficulties in addition to those characteristics of general communicable disease reporting. This paper will describe how a group of North Carolina physicians view this problem. These physicians were questioned about the extent to which they reported cases of syphilis, their reasons for reporting or not reporting, and their opinions on the proper use of case reports by health departments. The interviews were carried out in the course of a more comprehensive survey of public health problems in the management of syphilis by private physicians.

Syphilis case reports are needed by official health departments as an index of the extent of the syphilis problem and also as a basis for initiating specific preventive action—particularly contact investigation. At present many authorities believe that, because of the lowered

cost of treatment, an increasing proportion of patients with early syphilis are seeking treatment from private physicians rather than from free clinics sponsored by health departments (1). If this is true, organized syphilis control activities may become increasingly dependent on the accuracy and completeness of physicians' reports.

Collection of Data

Our data consist of what physicians said about their own practices, opinions, and attitudes. Systematic observations of their work were not done as part of this study. Our principal informants were 74 practicing physicians in 5 counties and 2 cities of central North Carolina. These physicians included all general practitioners and internists practicing in the 5 counties and in 1 city (25,000 population), excluding a few physicians from these areas who were interviewed during the pretesting of the interview schedule. The physicians from the other city (70,000 population) included all Negro general practitioners and internists and a sample constituting one-third of all white general practitioners and internists (exclusive of the full-time staff of a teaching hospital) chosen at random. Of the total of 74 physicians, 64 were general practitioners and 10 were internists; 59 were white and 15 were Negro. Four well-organized local health departments served the study area.

Pretesting interviews were carried out during the winter of 1951-52 with a separate group of 27 private physicians and 8 public health

Major Taylor, formerly instructor in public health administration, School of Public Health, University of North Carolina, Chapel Hill, is with the Walter Reed Army Institute of Research, Walter Reed Army Medical Center, Washington, D. C. Dr. Wright is professor of public health administration, University of North Carolina School of Public Health.

organizations have sponsored national cancer conferences at which all aspects of the problem have been reviewed and new developments in research and therapy brought to public attention. The third National Cancer Conference was held in Detroit, June 4-6, 1956, and was attended, in addition to United States leaders in this field, by a distinguished contingent of cancer specialists representing 22 foreign countries. Also, to give all possible assistance when requested by proper authorities in foreign

countries, the American Cancer Society has in operation a board committee and foreign desk to maintain liaison with the Department of State and foreign embassies and to answer queries from abroad. More than 500 requests for information were received from 69 countries in 1955.

Thus the society, while pursuing its own threefold goal of research, education, and service, acts as a national and international catalyst to end the scourge of cancer.

INTERNATIONAL MAIL POUCH

Inoculation—Local Style

In remote sections of Afghanistan, which is larger than Texas, it has been the practice of "mullahs" to inoculate villagers with matter from pustules of patients with active smallpox. Many villagers bear scars on the dorsum of the hand between the first and second metacarpals as evidence of this practice. Near Lashkar Gah, one such mullah practicing his art left a wake of dead children, hand infections, and axillary abscesses, products of a combination of smallpox and septicemia. The Lashkar Gah staff saved many children, but the mullah escaped.

"Stamping" Out Malaria

The Government of India has issued a 6-anna postage stamp bearing the legend "malaria control" with two scenes: one depicts poverty in malarious areas, the other shows prosperity after DDT. With

a history of more than a million deaths annually from malaria, India is waging a large and successful control campaign.

—JOHN J. HANLON, M.D., *chief, Public Health Division, International Cooperation Administration.*

Rural Health Teams

Extension of rural health services in the Philippine Islands has reached the point where more than a third of the smallest governmental units have the basic team of physician, nurse, midwife, and sanitary inspector. Two-thirds have at least three of the team. More than 9 in 10 had at least one public health official. Training centers plan to provide field experience for more than 7,000 community development workers. Malaria control has progressed to the point where housewives question the need for further spraying of their walls since none of the family has had the fever for a year.

—MALCOLM J. FORD, M.D., *rural health adviser to the Republic of the Philippines.*

Table 2. Factors influencing physicians' decisions not to report or to report syphilis cases as a general rule or in individual instances

| Factors influencing decision | Number of physicians replying | Percent of 74 physicians |
|---|-------------------------------|--------------------------|
| <i>Not to report</i> | | |
| Fear that information about patient will not remain confidential | 29 | 39.2 |
| High status of patient or personal friendship of physician for patient | 10 | 13.5 |
| Hostility to "making reports" and "red tape"; indifference; "no reason" | 10 | 13.5 |
| Various clinical characteristics | 5 | 6.8 |
| Ability of patient to cooperate with physician | 2 | 2.7 |
| Miscellaneous | 5 | 6.8 |
| <i>To report</i> | | |
| Legal requirement to report | 20 | 27.1 |
| Recognition of health department's need for case reports in order to carry out control measures with individual patients and families | 19 | 25.7 |
| Recognition of health department's need for case reports for statistical studies | 11 | 14.9 |
| Inability of patient to cooperate with physician | 9 | 12.2 |
| Patient being referred to health department for treatment | 7 | 9.5 |
| Various clinical characteristics | 5 | 6.8 |
| Miscellaneous | 5 | 6.8 |

locked up and we have found evidence that the janitor and janitress have looked through records."

"A few prominent patients would be reported as 'X' rather than by name. This is because they know people who work in the health department. In a small town you have to consider this even though the clerk in the health department here is a very fine person."

"One of my patients had a blood test done which was negative. A friend of hers, who worked in the public health lab, told her, 'I saw your blood going through.' I figured this friend might tell if someone had a positive test, so I use numbers and don't report by name."

The patient's status was cited by 10 physicians (14 percent) as a factor influencing their reporting practices.

"If the patient was a friend or an outstanding person in the community I wouldn't report his name to the health department. No good would be accomplished by having it publicized."

Ten physicians mentioned the work involved

in reporting or said they simply neglected or forgot to report cases.

"I have no scruples against it. I just don't do it."

"It takes too much time and red tape. I know the statistical value and contact tracing value, but there is too much time required of the doctor and no compensation given."

Two physicians stated that cooperation on the part of the patient in following orders would influence them not to report while nine physicians stated the converse—that lack of cooperation would influence them to make a report. Case holding during therapy itself is no longer the problem it once was; however, adequate followup is still a long-term process which does require understanding and cooperation by the patient.

Certain clinical characteristics of individual patients were named as reasons for "not reporting" by five physicians. These were "old cases," "partially treated cases," "cases with a 'doubtful' blood test," and "noninfectious cases." Other clinical characteristics were named by five physicians as reasons "for reporting." These were "prenatal patients," "infectious cases," and "seroresistant cases." In general, the first group of characteristics suggests less urgent need for action on the part of the health department than does the second group of characteristics. This is an encouraging finding; however, it would not be justifiable, on the basis of these data alone, to conclude that all or even most of the cases regarding which the health department should take action would be selected by the physician for reporting.

In general, the interviewer gained a distinct impression that physicians were uncertain about how to answer the question: "Why do you report?" Lack of cooperation by the patient and the clinical characteristics of the case have been mentioned. The most frequent answers were that reporting was required by law, that reports were needed for control measures centered around the individual case (for example, contact investigation and followup), and that reports were needed for statistical studies (table 2). But to the interviewer, the answers seemed vague, and few concrete examples were given from the doctor's own experience.

physicians from the same general area. The 74 standardized interviews were carried out in April and May 1952.

In the analysis of data, physicians' answers were grouped together in appropriate categories. Sometimes more than one answer would be given to a question, the informant indicating alternative actions he might take under various circumstances. Therefore, percentages of physicians giving various types of answers may add to more than 100 percent. During both pretest and standardized interviews, many of the comments by physicians were written down verbatim. Examples will be given to illustrate the kinds of individual response grouped into particular categories.

Response by Physicians

Physicians were asked whether they would report their syphilis cases by name to the health department. Answers were immediately classified by the interviewer according to a scale, as shown in table 1. Over one-third of the physicians claimed to report all cases, while less than one-tenth of the group asserted they never reported a case. On the other hand, two-thirds admitted failure to report at least some cases. The most important fact emerging from table 1 is that it tends to confirm the presence of a real problem centered in the reporting process.

Reporting Practices

Depending on their initial answer, physicians were asked alternative questions as to why they did or did not report syphilis cases. Answers to these questions are summarized in table 2. Doubts as to the confidentiality of reports and the closely related factor of patient status were the outstanding reason for "not reporting" cases, followed by indifference or hostility to the administrative paper work required. Outstanding among reasons "for reporting" cases were an awareness that "it's the law," plus recognition of the value of case reports to the health department (a) for carrying out specific control activities or (b) for statistical studies.

Twenty-nine, or about 40 percent, of the physicians expressed concern that the identity of their patients would not remain secret and that patients would suffer as a consequence.

Table 1. Physicians' answers to question: "When you find that a patient has syphilis do you report his name to the health department?"

| Reply | Physicians replying | |
|--|---------------------|---------|
| | Number | Percent |
| Report all cases | 26 | 35.2 |
| Generally report, sometimes do not report | 17 | 23.0 |
| No general policy or tendency | 6 | 8.1 |
| Generally do not report, sometimes do report | 19 | 25.7 |
| Never report a case | 6 | 8.1 |
| Total | 75 | 100.1 |

Reasons given by individual physicians for this fear included:

1. Chances of improper disclosure multiply as each additional person has legitimate access to information.
2. Health department clerks are not adequately trained in medical ethics.
3. Health department offices sometimes are not physically adequate for protection of confidential information.
4. Though the health department employee may keep information confidential, his own knowledge may harm the patient indirectly, particularly in small towns and rural areas.
5. Specific incidents, not necessarily involving a case of syphilis or even the health department, have impressed the physician with the speed of travel of gossip and rumor.

The following statements illustrate these points of view:

"Most people don't want everyone knowing they have syphilis. When three people know anything, it's out."

"I'm sure that the nurses and other trained persons at the health department keep things confidential. But the clerk is hired right here in town and has had no particular training. She might not keep things confidential."

A health officer interviewed during pretesting of the interview schedule: "Often the physical facilities are such in health departments that information cannot be kept confidential. . . . In my own health department, I share an office with five other persons. Sometimes it has been impossible to have records

initiated on the request of the private physician. However, 30 percent were uncertain, and 12 percent thought that the health department took independent action when a case report was made. Of the latter group of 9 physicians, 5 rarely or never reported cases; 1 usually reported his cases but was opposed to the health department's initiation of any control measures on the basis of the reports, and 3 physicians said they reported all cases and felt that the health department should proceed on its own initiative with contact investigation.

If a health department is to carry out control measures related to the private patient on whom a report of syphilis is made and yet is not going to bypass the physician, a basic action is to initiate discussion of the case with the physician. Health department and physician together must arrive at some working arrangement as to what is to be done, and by whom. A logical extension of this type of health department action is to contact the private physician who has submitted to the laboratory a blood sample which is positive to a serologic test for syphilis (STS)—if a case report is not received in 2 or 3 weeks. (To make this procedure practicable, a central file must first be checked to eliminate previously reported cases.) If the diagnosis is complete, assistance can be offered to the physician and a case report can be made immediately. If the health department laboratory performs most of the STS for the area, the completeness of case reporting and the extent

of use of health department control services should increase markedly.

At the time of the survey, none of the four health departments in the study area were carrying out the policy described. Since other areas of the country had reported success with such a policy (2), we endeavored to find out whether or not our informants would view it with favor. The answers of the 74 informants to this question are shown in table 5.

Table 5 suggests that the physicians were more favorable toward this specific type of health department action than toward the general idea of control activities directed at their syphilitic patients. Fifty-seven percent indicated they were in favor of the policy outlined, 26 percent were opposed to it, and 18 percent made comments that could not be definitely classified as favorable or unfavorable.

Interesting arguments were given for and against the hypothetical policy. Some physicians felt such a policy would be of definite help to them in clinical management and in preventing patients from being lost to medical observation:

"This would be an excellent policy because we lose patients. My partner and I see 70 to 80 patients a day. When we get through the day we don't have time to trace people down. I write the patients letters and they ignore them. The public health nurses could get out and run them down."

"This policy would leave no loopholes. It would make sure the doctor gets the blood test report. It would find whether or not the health department can be of help. It would save the doctor time. This is a factor in general practice."

Other physicians felt that the hypothetical policy would be unnecessary and expensive:

"It would be all right. But I feel the measures already being done are handling the problem pretty well. I used to find 15 percent positive tests, and only about 1 percent now."

"It seems to me there would be a duplication of effort. Here we try to reduce the health department work to a minimum. I feel this policy would not be necessary."

Again, some doctors felt that initiation of discussion of the case by the health department would be an objectionable interference in the physician-patient relationship, some mentioned their dislike of having the government involved in their work, and some objected to the

Table 4. Physicians' answers to question: "In this county, does the health department usually contact the patient or his family directly when a doctor reports a case of syphilis?"

| Reply | Physicians | |

| | Number | Percent |
| No, health department does not usually contact patient or family directly..... | 42 | 56.8 |
| Not certain or do not know..... | 23 | 31.1 |
| Yes, health department usually does contact patient or family directly..... | 9 | 12.2 |
| Total..... | 74 | 100.1 |

"It's the law."

"The only reason I know for reporting is that public health has helped by taking over syphilis. There used to be many inadequately treated cases."

"I feel cases should be reported. I'm not sure why. I have just been led to that opinion by the health department."

Seven physicians mentioned that some cases would be reported merely as a part of the process of referring them to the health department for treatment. Finally, a variety of miscellaneous reasons were cited by a very few physicians each to explain why cases were or were not reported. A few are of possible importance though not mentioned frequently by our informants, for example:

"The reporting of infectious disease has been backsliding for years. It's silly to report measles and chickenpox. This attitude carries over to the reporting of syphilis. We report polio, typhoid, TB—but we don't report syphilis as well as we should."

As stated above, our informants recognized certain uses which a health department might make of case reports. Additional questions were asked to learn more about physicians' concepts of the role, actual and desirable, of the health department in control measures aimed at the private patient.

Health Department Control

Forty-nine physicians, excluding the 25 who never or only rarely make a case report by name, were asked: "In your opinion, should the health department take any action when a private doctor reports that one of his patients has syphilis?" The type of "action" which might be taken was purposely left unspecified. Answers are shown in table 3.

The majority of the physician informants had reservations about health department "action" (table 3). One-tenth said that the health department should take no action and mentioned no exception. About 40 percent said action should be taken only on the specific request of the private physician. And it is probably fair to say that the one-third who rarely or never report their cases would also be opposed to the health department taking any part in the management of their private patients. Finally, a minority of 10 (14 percent) informants voiced definite opinions that the health

department should take specific types of action—investigation of contacts, followup of patients to insure adequacy of treatment, or education of the patient.

A possible explanation for physicians' reluctance to have the health department carry out specific control measures with private patients is that the physicians are uninformed or misinformed as to what this action might be. For example, physicians have traditionally feared and opposed any third person working independently with their patients, thus possibly interfering in the physician-patient relationship.

Actually, according to the health officers, all four local health departments in the areas surveyed followed a policy of not making any contact with the patient or members of his family, except with the approval of the private physician. To study physicians' knowledge of this policy, all 74 informants were asked: "In this county, does the health department usually contact the patient or family directly when a doctor reports a case of syphilis?" Answers are summarized in table 4.

The majority (57 percent) thought, correctly, that the health department did not contact the patient or family directly, that any contact was

health department taking the initiative away from them:

"I think it would be a good thing but I just don't like government interference."

"I wouldn't like this. It's better to leave it up to the doctor. This policy takes the initiative away from the doctor—undermines his interest in the case. And as a general rule the doctor will take more personal interest than the health department will in the patient."

One internist who favored the policy in general thought it should not be applied too rigidly. If the health officer had confidence in a particular doctor, he could assume that that doctor would "carry through with what was needed." If another doctor had not shown too much interest in syphilis, it might be necessary for the health officer to "keep in pretty close touch with him."

In summary, tables 3-5 suggest that physicians were suspicious of the general idea of health department participation in patient management (table 3); however, at the time of the interviews, they generally did not feel that the health department was participating to an objectionable degree (table 4); and finally the majority were willing for the health department to participate to a greater degree by at least initiating inquiries of the physician based on positive STS reports (table 5).

Discussion

Many problems and issues arise in the process of obtaining and using syphilis case re-

ports. The data presented have bearing on several of these problems.

Completeness of Reporting

The first and most important problem pertains to completeness of reporting. We cannot make a numerical estimate of the completeness of reporting by our informants, but it appears reasonable to conclude that many cases were not being reported.

This general conclusion is in agreement with a number of studies from other areas and periods of time. Rack (3) studied a series of 436 cases of syphilis from the Eastern Health District of Baltimore discovered by private physicians during 1932-37 and found that only 71, or 16 percent, had been reported to the Baltimore City Health Department. The Report of the WHO Syphilis Study Commission (4) states that in the United States "reporting by private physicians is variable, and, from our information, appears to be low." Lentz and Beerman (5) in 1952 mailed a questionnaire to all physicians known to be in private practice in Philadelphia. Replies were received from 75 percent of the physicians, who indicated that in 1951 they had treated 3,112 cases of syphilis. During the same period, the Philadelphia Department of Public Health had received reports for only 753 cases—less than 25 percent of the total treated, even assuming that physicians not replying to the questionnaire had discovered no syphilis.

Judging from the information received from our informants, the most serious obstacle to complete reporting is the desire of patient and physician to keep the diagnosis of syphilis a secret. The stigma attached to venereal disease has probably decreased in recent years, but it is unlikely to disappear entirely. Apparently, the physician often feels he must choose between a risk to his patient which is concrete, obvious, and within the physician's experience and a possible value to the community which is vague at best.

Keeping Reports Confidential

Certain steps can be taken by a health department to insure that case reports remain confidential. Physical inadequacies which make records and files accessible to unauthor-

ized persons can be attacked directly. Clerical and other personnel can be given additional training and supervision in the handling of confidential records. If these accomplishments are brought to the attention of physicians, they may feel free to submit more complete reports.

But there are limits to how effective these measures can be. When the health department employee who receives a report of a case of syphilis is a personal acquaintance of the syphilitic patient, harm may have been done the patient even if information travels no farther. This will be a particular problem in rural areas and small towns. And despite all precautions, the length of the route of communication in the reporting process (doctor's office to local health department to State health department) allows many possibilities for information to be diverted into improper pathways.

High social status of the patient and his willingness to cooperate with the physician influence the latter's decision not to report a case of syphilis. These factors cannot be altered directly by health department action, except by the above measures and by any other action which gives the physician and his patient greater faith in the confidentiality of the reporting process.

Simplifying Reporting

Some informants complained about the "red tape" of the reporting process. It is true that somewhat more effort and specialized knowledge are required to complete the usual syphilis report form than to make a report of most of the other communicable diseases. Possibly the total volume of paper work required of the physician could be reduced by eliminating so-called compulsory, but probably very incomplete, reporting of some of the common communicable diseases, such as measles, for which there is no very effective control program in operation.

This would leave the physician with more time for, and possibly more interest in, the reporting of diseases, such as syphilis, which are more important from the standpoint of specific preventive action which can be taken by the health department. The American Public Health Association's manual, *Control of Communicable Diseases in Man* (6), has re-

cently reenphasized that: "Diseases are often made reportable although the information gathered is put to no practical use. This frequently has the result that the general level of reporting deteriorates, even for diseases of much importance. Better case reporting is usually to be had by restricting official reports to those diseases for which control services are provided, or potential control measures are under evaluation, or epidemiological information is needed for a definite purpose."

Reasons for Reporting

While our informants had quite substantial reasons for "not reporting" syphilis cases, their reasons "for reporting" seemed vague and unconvincing. The health department may be able to take steps which will increase physicians' positive motivation to report cases.

Despite the fact that all States require that syphilis be reported, the law is seldom enforced. Nor does it seem likely that attempts at real enforcement would be successful.

It may be possible to increase physicians' interest in contributing to good statistical data. We have no definite recommendations for accomplishing this. A means will have to be found to make syphilis morbidity data of more concrete interest and value at the local level. At present, if the physician does see the data he has contributed, it is usually in the form of consolidated figures for State or Nation. He may see local rates in his health department's annual report, but these also are not of dramatic interest, and they lack the respectability associated with large numbers.

Next to the legal requirement, the factor most frequently mentioned as influencing our informants to report cases of syphilis was an awareness that the health department needed the reports to carry out certain control measures with individual cases. A health department should make it clear to private physicians that, with rare exceptions, staff members do not attempt to carry out these measures without notifying and coordinating their efforts with the physician. This knowledge should help the physician who fails to report a case because he fears the health department will harass the patient. Also it will be of interest to the occasional physician who expects and wants the

health department to go ahead routinely with such procedures as contact investigation and followup when he makes a case report. He should know that if he wants these procedures done he must specifically request them.

Use of Laboratory Records

Despite all the various measures which can be suggested to improve reporting, it seems unlikely that complete reporting can be achieved on a voluntary basis. Reporting can be made a more nearly compulsory procedure if the health department has access to a large part of the reports of STS done in the area, and if it uses these as the basis for case reports. For this procedure to be completely successful, the health department laboratory must perform most of the STS done in the area, or there must be a voluntary arrangement giving the health department laboratory access to positive STS reports from private laboratories. A recent Public Health Service manual gives a clear outline of the details of this reporting system (7).

The majority of our informants were in favor of the laboratory records of positive STS being used in this way (table 5). The health department carrying out such a policy must decide how much time and effort can be devoted to it. The work can be kept to a minimum. Report cards can simply be mailed to a physician for each patient on whom a positive STS report is received and for whom no case report is on file. Or a great deal of effort can be expended. Physicians can be telephoned, and a case report can be made out at that time, making it convenient for them to request information about clinical problems or help in followup and contact investigation. As suggested by one informant, more time may need to be spent with some physicians than with others. Or it may be of interest periodically to devote particular study and effort to specific types of cases, for example, infectious syphilis, or perhaps central nervous system syphilis.

Actually, according to a personal communication dated June 4, 1956, from Dr. Warfield Garson, chief, venereal disease section, North Carolina State Board of Health, since 1953 (about 1 year after this survey) the general procedure outlined has been carried out in

North Carolina with STS reports emanating from the State laboratory of hygiene.

Whenever a case of possible primary or secondary syphilis is brought to the attention of the State board of health through surveillance of laboratory reports, a confidential serology report is routinely sent to the county health officer in the physician's area. The health officer is requested to contact the private physician concerning reporting the case and to offer consultative, diagnostic, and epidemiological aid. In many instances, a venereal disease investigator on the staff of the State board of health or the county health department gets in touch with the physician and attempts to make a working arrangement for carrying out contact investigation and other indicated public health measures. These procedures have allowed for an increase in private physician reporting of syphilis from 7 percent of the total cases in 1953 to 35 percent in the fiscal year 1956.

As suggested by our informants, some physicians may resent this type of health department action. Depending on local circumstances, the benefits may or may not be worth the price. Additional physicians may begin to send their blood specimens to private laboratories in order that the health department will have no record of the tests. Others may choose to use initials or code numbers instead of correct names on the laboratory slip. However, when this happens the health department could still conceivably discuss the case with the physician, clinical and epidemiological problems could be reviewed, and contacts could be reported for investigation.

Summary

During a survey of public health problems in the management of syphilis by private physicians, 101 private physicians and 8 public health physicians in central North Carolina were interviewed. This report discusses survey findings relating to case reporting. Results are based chiefly on interviews during 1952 with 74 private physicians who answered a set of standardized questions.

Two-thirds of the 74 informants indicated that they did not submit case reports on some of their private syphilitic patients. The most

frequent explanation for "failing to report" cases of syphilis was fear that the information would not remain confidential.

Most frequent reasons "for reporting" cases were that it was legally required, that the health department needed reports in order to carry out specific control procedures, and that reports were needed for statistical studies.

The majority of informants said they would be in favor of the health department using positive reports of serologic tests for syphilis (STS) on blood samples sent to the public health laboratory, as a basis for case reports. However, a sizable minority were opposed to or undecided about this procedure.

The findings of this survey cannot be applied uncritically to other areas. However, certain lines of action by health departments to improve syphilis morbidity reporting are suggested:

1. Do everything possible to protect the confidentiality of syphilis case reports. Consider physical protection (files and locks), the number of people having access to reports, and the training of personnel in medical ethics. Let physicians in the community know the measures being taken to keep reports secret.

2. Restudy the entire communicable disease reporting system and, where possible, eliminate paper work required of the physician.

3. Try to devise ways for making good statistical and epidemiological use of case reports in the local community so that physicians can see the contribution they are making when they report cases properly and completely.

4. Let physicians know that the health department does not attempt to work directly with individual private patients without the physician's knowledge and permission.

5. Consider the advantages (and disadvantages) of using laboratory reports of positive STS as a basis for obtaining complete or nearly complete case reports, for making services such as contact investigation, followup, and clinical

consultation easily available, for keeping in touch with the relative quality of syphilis management in private practice, and for making occasional special studies of particular types of cases.

This paper is the eighth in a series of reports on the North Carolina Syphilis Studies. The organization and original field of operation were described in a report published in the February 1949 issue of the Journal of Venereal Disease Information. The present study area included the original area plus two additional counties and one additional town. The study was supported by the Division of Venereal Disease of the Public Health Service, the North Carolina State Board of Health, and the School of Public Health of the University of North Carolina.

technical publications

Directory of State and Territorial Health Authorities, 1956

*PHS Publication No. 75.
Revised 1956. 86 pages,
35 cents.*

Revised annually, this directory lists, as of May 1956, the title and location of each State health department and the name of the officer in charge; organizational units of individual States with the names of officials directing the units. Also included are officials of State agencies other than health agencies directing grant-in-aid programs; and State agencies officially designated for the administration of the Water Pollution Control Act and crippled children's services.

Personnel of the Public Health Service in charge of functions closely associated with State health departments are listed in the appendix.

Research Grants and Fellowships Awarded by the Public Health Service in 1955

*PHS Publication No. 469.
1956. 83 pages. 30 cents.*

This annual report lists the research grants and fellowships awarded by the Public Health Service to non-Federal institutions and to individuals for support of research and training in medical and related sciences for the period July 1, 1954, through June 30, 1955.

A preliminary statement explains briefly the entire awards program and summarizes the awards by the seven categorical institutes and the Division of Research Grants for fiscal 1955.

The listings are alphabetically arranged by State or countries, institutions, and investigators or fellows.

Following the name of the investigator is a brief descriptive title of the research, an identifying number which indicates the supporting institute, and the funds awarded for fiscal 1955. Names of fellowship recipients are interspersed alphabetically among research investigators. The type of fellowship, the department of the institution in which the recipient holds his fellowship, and the sponsoring institute are indicated.

Vital Statistics of the United States, 1954 Volume I

*NOVS Publication.
422 pages. \$3.75.*

This volume contains detailed, final statistics for 1954 on marriage, divorce, birth, and fetal and infant mortality for the United States, each State, each county, certain cities, Alaska, Hawaii, Puerto Rico, and the Virgin Islands. Summary tables of rates and percentages and an explanatory text are also included.

An extensive introduction explains sources, classification, and interpretation of data, and columns of the life tables.

Issued previously, volume II (1956) comprises particular statistics of mortality in 1954 by State, cause, race, sex, and age, for the areas listed above.

Operational Memoranda on Economic Poisons

*PHS Publication (unnumbered).
1956. 99 pages. Multilithed.*

A guide to the use of public health pesticides, this revised edition describes 23 of the newer insecticides and rodenticides.

It gives the chemical name, chemical formula, physical properties, formulations, precautions, and use experience. Information on approximate costs and tabular data on formulations and measurements is also included.

Public health officials who plan or conduct insect or rodent control programs should find this booklet particularly useful.

Copies can be obtained from the Communicable Disease Center, Public Health Service, Atlanta 23, Ga.

An Outline Guide Covering Sanitation Aspects of Mass Evacuation

*Public health problems in
civil defense*

*PHS Publication No. 498.
28 pages. 1956. 50 cents.*

This booklet is intended as an aid to Federal, State, and local health and civil defense agencies in developing comprehensive plans for sanitation, should it become necessary to move urban populations to rural territory.

The expanded outline covers methods of protection from radioactive fallout for evacuees during transit, at assembly areas, in temporary shelters, and in reception areas.

The publication also defines civil defense terms and describes emergency sanitation procedures.

This section carries announcements of all new Public Health Service publications and of selected new publications on health topics prepared by other Federal Government agencies.

Publications for which prices are quoted are for sale by the Superintendent of Documents, U. S. Government Printing Office, Washington 25, D. C. Orders should be accompanied by cash, check, or money order and should fully identify the publication. Public Health Service publications which do not carry price quotations, as well as single sample copies of those for which prices are shown, can be obtained without charge from the Public Inquiries Branch, Public Health Service, Washington 25, D. C.

The Public Health Service does not supply publications issued by other agencies.

North American Blastomycosis in an Epidemic Area

By JEROME S. HARRIS, M.D., J. GRAHAM SMITH, JR., M.D., WALTER C. HUMBERT, M.D.,
NORMAN F. CONANT, Ph.D., and DAVID T. SMITH, M.D.

AFTER 10 patients with North American blastomycosis, all from the same area in Pitt County, N. C., were admitted within a month and a half to Duke Hospital, we thought a survey for blastomycosis would be desirable.

Since the epidemic included a child as young as 7 years and a man aged 77 (1), plans were made to examine all persons within a 4-mile radius from the center of Grifton in Pitt County. About 750 were expected. Knowledge about the epidemic became so widespread and community interest so intense, however, that 1,648 people appeared. Many came from nearby areas. The survey was conducted during the week of April 12-16, 1954.

Methods of Study

The survey included skin tests with *Blastomyces* vaccine, histoplasmin, and old tuberculin; complement fixation (CF) tests of blood specimens; and 70-mm. chest X-rays. Children

Three of the authors are associated with Duke University School of Medicine. Dr. Harris is chairman, department of pediatrics; Dr. D. T. Smith is chairman, department of microbiology; and Dr. Conant heads the mycology laboratory. At the time of the study Dr. J. G. Smith was an instructor in the division of dermatology and syphilology, department of medicine, Duke University School of Medicine. At present he is an instructor in the division of dermatology, University of Miami School of Medicine. Dr. Humbert is health officer of Pitt County (Greenville), N. C.

under 6 years were not X-rayed because of the technical difficulty in taking satisfactory pictures, but children in that age group were skin tested. When feasible, their blood samples were obtained also.

The *Blastomyces* vaccine and histoplasmin tests were placed on the right forearm at widely separated points. The tuberculin tests were made on the left forearm.

A 0.1 ml. portion of each of the 3 antigens was injected intracutaneously. In no instance were different antigens used in the same syringe. All syringes were new and were marked with a diamond point to indicate which antigen was to be used. After initial use each syringe was resterilized with other syringes used for the same antigen. The syringe was autoclaved before it was refilled.

The skin tests were read by measuring the diameter of areas of erythema and induration with a millimeter ruler. Skin tests were considered positive when induration was 5 mm. or more, or doubtful when erythema was 10 mm. or more and induration less than 5 mm. All other results were considered negative.

Because of the unanticipated response to the survey, it was necessary to use 3 lots of histoplasmin. Patients (group 1) numbered 1 to 650 were tested with lot HKC-5 diluted 1:500. Patients (group 2) numbered 651 to 1,200 were tested with lot H-42 diluted 1:100, and patients (group 3) numbered 1,201 to 1,648 were tested with lot H-42 also, but the histoplasmin was diluted 1:1,000.

Lot HKC-5 and lot H-42 of histoplasmin

were supplied by Dr. Michael L. Furcolow, chief of the Kansas City Field Station of the Communicable Disease Center, Public Health Service.

Undiluted old tuberculin (Wyeth, Inc.) was supplied by Dr. William M. Peck of the North Carolina Sanatorium for Tuberculosis at McCain and was diluted 1:1,000 before use.

The *Blastomyces* vaccine was prepared in Dr. Conant's laboratory from 6-day yeast phase cultures grown in brain-heart infusion on blood-agar slants at 37° C. The yeast cells were then killed by suspension for 2 hours in a saline solution heated to a temperature of 56° C. The vaccine dilution, though not strictly an extract, will be referred to hereafter as blastomycin.

CF tests with *Blastomyces* antigen were performed by Dr. Joseph Schubert at the laboratories of the Communicable Disease Center, Public Health Service, Atlanta.

Results of Tests

Logistic difficulties made it impossible to test everyone with each antigen; therefore 1,465 persons were tested with blastomycin, 1,383 with histoplasmin, and 1,325 with tuberculin. Forty-two had positive reactions to blastomycin (2.9 percent), 88 to histoplasmin (6.4 percent), and 340 to tuberculin (25.6 percent.)

The fact that acquired histoplasmin sensitivity in some persons will give a cross reaction to blastomycin is well known (2, 3). On the other hand, the converse situation of a positive blastomycin skin test with a negative histoplasmin skin test has been observed not in-

frequently at Duke Hospital in patients with clinical blastomycosis though similar instances have been reported rarely in the literature (4, 5). Of the 1,380 persons tested with both histoplasmin and blastomycin in the survey, 11 had positive tests with both antigens and 27 had a blastomycin skin test of 5 mm. or more of induration and a histoplasmin test showing 4 mm. or less of induration (table 1). Despite the insignificant reactions to histoplasmin, in 6 of the 27 induration from the blastomycin was larger than 10 mm. Conversely, 77 individuals reacted to histoplasmin but not to blastomycin. Thirty-two of these had more than 10 mm. of induration with histoplasmin. The degree of cross sensitivity must, therefore, be small.

As previously noted, 3 histoplasmin antigens were used in the survey: HKC-5 diluted 1:500, H-42 diluted 1:100, and H-42 diluted 1:1,000 (tables 2, 3, and 4). Since H-42 1:100 and HKC-5 1:500 were considered to give analogous reactions, no comparison of the relative size of induration was made (6). The difference in size of reaction to H-42 1:100 and H-42 1:1,000 might be of considerable magnitude, however.

To test that possibility, 13 persons, most of whom were known to react positively to histoplasmin, were tested with 1:1,000 and 1:100 dilutions of lot H-42. The more concentrated solution was injected into the right forearm of 7 individuals and into the left forearm of 6. Both tests were negative in 3 of the 13 persons, but in 3 others induration measured less than 5 mm. with the 1:1,000 dilution and more than 5 mm. with the 1:100 dilution. The remaining

7 had positive reactions to both antigens, but in general the induration was several millimeters larger at the site of the 1:100 dilution.

Dependence of reactivity on the concentration of the dose was also evident in the 3 test groups. Eighty-eight, or 6.36 percent, of all 1,383 individuals tested with histoplasmin were positive. The percentage of positive reactions in group 1 was 6.69 (41÷613, table 2). The percentage in group 2 was 7.57 (29÷383, table 3) whereas in group 3 it was 4.65 (18÷387, table 4). The lower percentage of positive reaction in group 3 may have resulted from the more diluted antigen of histoplasmin.

Nevertheless, the variable of a more dilute antigen in the 387 tests in group 3 does not influence the preceding conclusions concerning cross reactions since only 8 of the 27 individuals with positive blastomycin and negative histoplasmin reactions were tested with the weaker strength of histoplasmin. Seven of the eight

had no reaction to the histoplasmin. Since all controls having a positive reaction to the more concentrated dose of histoplasmin also had some induration from the weaker material, it is doubtful that the 7 would have shown positive reactions to the 1:100 dilution. The individual who showed less than 4 millimeters of induration from the 1:1,000 dilution might have been definitely positive to histoplasmin if he had been injected with the 1:100 dilution. However, that possibility would not invalidate the general conclusion that individuals can be highly sensitive to blastomycin without demonstrating histoplasmin sensitivity. The frequency of the converse situation (histoplasmin sensitivity and blastomycin negativity) is obvious from the tables.

On the other hand, some degree of association between histoplasmin and blastomycin sensitivity in a population can be shown statistically from probability tables. For example, from

Table 2. Blastomycin and histoplasmin reactions in group 1: histoplasmin lot HKC-5 diluted 1:500

| Blastomycin (mm. induration) | Histoplasmin (mm. induration) | | | | | | | Total |

| Total | 310 | 44 | 19 | 8 | 2 | | 60 | 443 |

table 5 it can be seen that considerably more persons reacted positively to both antigens than can be explained on a random basis from the number of reactors to each antigen separately. Eleven individuals reacted to both antigens whereas only 2.4 would have been expected in this group. The difference is highly significant statistically (chi square equals 30.0).

This association may be caused not only by a general hypersensitivity of the skin in these individuals or by a similarity in the antigenic components in the two test materials, but also by a common mode of spread of the diseases so that there would be a statistically significant increased probability of exposure to both diseases over the random chance of acquiring the two on independent bases. Of the 11 individuals who reacted to both blastomycin and histoplasmin, 7 had negative tuberculin tests, 3 had positive tuberculin tests, and 1 was not tested for tuberculosis. These figures are similar to those of the general population and do not indicate general hypersensitivity of the skin in these indi-

viduals. The failure of the blastomycin and histoplasmin tests to show cross reactivity in 101 individuals out of the 115 that were positive for either test (table 5) speaks against the presence of strong common antigens while recent reports of simultaneous infections with blastomycosis and histoplasmosis in humans and dogs is strong evidence for the last postulate of a common mode of transmission (7, 8).

The age variation in the percentage of reactors in the study of tuberculin, histoplasmin, and blastomycin is shown in the figure. The high prevalence and rapid increase of tuberculin sensitivity with age is well known for Pitt County. The graph shows a gradual and poorly defined increase in both histoplasmin and blastomycin reactivity with age. The poorly defined histoplasmin reactivity is in marked contrast to the conditions pertaining in the Mississippi Valley areas (9). The lack of correlation between the reactions of tuberculin and of histoplasmin or blastomycin sensitivity is well demonstrated by the chart.

Table 4. Blastomycin and histoplasmin reactions in group 3: histoplasmin lot H-42 diluted 1:1,000

Variation with age in prevalence of positive skin reactions to tuberculin (TBC), histoplasmin (Histo.) and blastomycin (Blast.).

Blastomycosis CF tests were performed on 1,275 serums of the 1,648 individuals in the survey. Twelve serums were anticomplementary, 1,220 were negative, and 43 were positive to the CF tests. The titers ranged from undiluted to 32-fold dilutions. The number of positive skin tests in each group showing different degrees of titer are presented in table 6. Complement fixation showed no obvious correlation with blastomycin or tuberculin skin sensitivity. However, although the percentage of positive tuber-

culin tests and of positive blastomycin tests in the group showing complement fixation is similar to the percentage in the general study population, the percentage of histoplasmin reactors is much greater in the former group (30.2 percent) than in the latter (6.4 percent). Further, the individuals having positive CF titers failed to show a much greater prevalence of positive blastomycin skin sensitivity than did the general population (table 6). The significance and meaning of these observations await clarification.

The survey included 1,465 (70 mm.) fluorophotographs; 1,393 (95.1 percent) were negative, 4 were unsatisfactory, and 68 showed some evidence of pathology involving either the heart or lungs. Forty-six large roentgenograms were taken of suspicious lung lesions. However, although many small scars were noted, only one individual was found to have active pulmonary tuberculosis. This result was most surprising in view of the high percentage of tuberculin reactors (25.6 percent) in the study population. Only 17 of the 72 individuals with suspicious fluorophotographs had positive tuberculin tests, 6 had positive histoplasmin tests, and 6 were positive to blastomycin. No instances of pulmonary blastomycosis or histoplasmosis were uncovered although a 31-year-old male who moved to Grifton one month (March 1954) before the survey developed cough and chest pain shortly thereafter. He did not attend the

Table 6. Relationship between skin sensitivity and Blastomyces complement fixation test

| Complement fixation titer | Persons with positive reactions | | | Persons with negative skin tests | Persons without skin tests | Total |

| Percent of total population showing positive skin tests | 25.6 | 6.4 | 2.9 | | | |

¹ Percent of total showing positive blastomycin complement fixation who showed a positive skin sensitivity test.

survey because of his recent arrival. In July 1951 he was diagnosed at Duke Hospital as having blastomycosis.

Summary

In an epidemic area in Pitt County, N. C., 1,618 individuals were surveyed for North American blastomycosis by Duke University School of Medicine. Blastomycin skin tests and complement fixation tests were made, and 70-mm. fluorophotographs were taken. Sensitivity to histoplasmin and tuberculin was determined simultaneously.

Of the population, 2.9 percent were sensitive to blastomycin, 6.4 percent were sensitive to histoplasmin, and 25.6 percent had positive reactions to tuberculin. The *Blastomyces* CF test did not correlate with skin sensitivity. No individuals with cutaneous or pulmonary blastomycosis were discovered, and only one individual with active pulmonary tuberculosis was found.

The correlation between blastomycin and histoplasmin sensitivity was carefully studied, but there was little evidence in this survey that antigens common to blastomycin and histoplasmin would explain completely the unexpectedly greater number (11) of individuals who were sensitive to both histoplasmin and blastomycin. The evidence may implicate a common mode of contact with the agents causing sensitivity to these two materials. There was no correlation

between sensitivity to tuberculin and sensitivity to either blastomycin or histoplasmin.

Dr. Charles-Edward Amory Winslow

February 4, 1877—January 8, 1957

Dr. C.-E. A. Winslow has made an immeasurable contribution; his genius and untiring efforts have placed an indelible mark on the entire world of public health. Many thousands of health workers, like myself, are forever indebted to his teaching, his guidance, and his wise counsel. To the generations that come after us, his wisdom will have an undying influence and stimulus. We have lost a great man whom we have loved, honored, and revered, and whose memory we will always cherish.

—Surgeon General Leroy E. Burney

Central Technical Services of the World Health Organization

By FREDERICK J. BRADY, M.D.

SOME of the technical services of the World Health Organization, which are carried on primarily from the headquarters in Geneva, have importance to the whole world. These activities have come about as the result of over a hundred years of attempts at international cooperation in those health matters that must be undertaken by nations working in concert.

The first abortive activity took place in 1851, when representatives of 12 nations met together to find common solutions to limiting pestilential diseases that periodically swept through most of the world. Unfortunately, in those early days there was no tradition of international cooperation, and the views expressed by delegates regarding the need to cooperate on health matters were not upheld by their governments. This was the beginning of a series of international conferences that, with the growth of scientific knowledge, began to bear fruit after a half century.

In international negotiations each participant, to gain objectives, must be prepared to relinquish certain prerogatives. We are fortunate in that objectives in health are similar for

all nations and that there is a high degree of understanding of each others' problems. This fortunate position has borne fruit in the World Health Organization and has been of immeasurable benefit in protecting the health of the American people. At the same time, health authorities of the various countries have not had to make major compromises, owing to agreement on ends.

WHO programs are varied, evolving from the early negotiations among nations which were concerned almost exclusively with problems related to international quarantine.

International Sanitary Regulations

At present the governments of 132 nations and territories have agreed to abide by the WHO International Sanitary Regulations that became effective in 1952. Twenty-four more governments are bound by these regulations with specific reservations that are published and known to the rest of the world. Eleven nations are not bound, and the position is uncertain in 12 others.

The International Sanitary Regulations are confined to six pestilential diseases, namely, smallpox, cholera, plague, yellow fever, typhus, and relapsing fever. The regulations were drafted not to impose on countries an unnecessary burden of measures to take against these diseases but rather to limit the measures nations could take in order to prevent the disruption of trade and travel while at the same time providing maximum security.

Dr. Brady is assistant chief of the Division of International Health, Public Health Service. His speech, in essentially the same form, was delivered at the annual conference of the National Citizens' Committee for the World Health Organization, November 14, 1956. The conference met with other groups in Atlantic City, N. J., at the 84th annual meeting of the American Public Health Association.

Until the regulations were adopted, 13 treaties and covenants dealing with quarantine were in effect. None was comprehensive in scope: Some were of a regional nature, and some applied solely to one disease or one type of transport. None was ratified by a sufficiently large number of countries. With the exception of the Pan American Sanitary Code, the regulations have replaced all previous treaties.

The International Sanitary Regulations are of great benefit to travelers from the United States because they give advance knowledge of what measures quarantine authorities in various countries may apply and also prevent overzealous authorities from taking unduly restrictive measures.

International Disease Reporting

Related to work on quarantine are the epidemiological intelligence activities of the World Health Organization. WHO regularly receives notifications of cases of quarantinable diseases which it then analyzes and transmits to health administrations, by radio bulletins and in weekly reports, thus providing health authorities with up-to-date knowledge on the distribution of quarantinable diseases.

The reporting program has been extended to other important communicable diseases and even to the degenerative diseases, making it possible for WHO to publish analyses and reports on their prevalence throughout the world.

Soon after its organization, WHO established an international system to detect any unusual outbreak of influenza lest a pandemic such as that of 1917-18 reoccur. The highly competent virus laboratories of the world form a network for reporting any unusual prevalence or virulence of the influenza virus. It is hoped that with adequate notice, vaccines can be prepared from dangerous viruses to keep outbreaks from reaching epidemic or pandemic proportions.

With the degree of protection afforded by the Salk vaccine, the prevalence of various strains of poliomyelitis virus assumes a new importance. It is also important to know whether presently unknown strains of poliomyelitis virus exist in the world. To meet these problems, WHO is encouraging virus laboratories

to determine the strains of poliomyelitis virus endemic in their localities and to watch for previously unrecognized strains.

WHO, as the coordinating authority in international health, is unique in its ability to collect, analyze, and compare health data from various parts of the world. The Organization presently is studying a proposal to organize registries of pathological tissues into a worldwide network, thus permitting interchange of specimens and diagnoses for comparative purposes.

Our knowledge of pathology is based almost entirely on specimens from Europe and North America. In the past we have generalized from these materials, assuming that our knowledge has universal application. In several diseases thought to be the same throughout the world, detailed descriptions of pathology lead to speculation whether the diseases observed are the same or whether similar but different diseases exist.

At this time it is not known in what area the World Health Organization will make a modest beginning in these activities, but one would expect that any disease chosen for study would have an unexplained, bizarre distribution pattern. One could foresee in this proposal an opportunity to further knowledge of pathological processes and also to provide unique opportunities for training.

International Drug Programs

International cooperation in dealing with drugs and other therapeutic substances has become a necessity. WHO activities relate particularly to the recommendation of standards for establishing common names and determining the purity and potency of drugs moving in international commerce.

Because some therapeutic substances of great importance in medicine today cannot be tested for purity and potency by physical and chemical methods, their analyses must be based on biological procedures. Unfortunately, biological standardization does not lend itself to the niceties of chemical or physical determinations but must take into account the variations in the response of living organisms used in tests.

Standard or reference samples become of great importance.

With the assistance of experts and cooperating laboratories from all over the world, WHO has so far established 66 biological standards for vaccines, serums, hormones, antibiotics, and enzymes. Standardization has resulted in providing international units that assure physicians the world over of the dosages they are prescribing.

Sometimes we are inclined to overlook the importance of national pharmacopoeias. Prescriptions for drugs were issued in ancient Egypt as long ago as 2800 B.C. Pharmacopoeias began to appear in Europe in the 16th century. The United States has had an officially recognized pharmacopoeia since 1893, serving as the basis for the purity and potency of our drugs.

Today, with the spreading use of modern drugs, at least 40 nations have official pharmacopoeias, which they revise from time to time, and other countries are preparing pharmacopoeias or specifications. There is a resulting urgency to achieve greater uniformity of standards so that the drugs will have comparable composition and potency no matter where they are produced.

While this problem has been a matter of concern to pharmacopoeial authorities for many decades, it was only after the World Health Organization came into existence that an international pharmacopoeia was completed. The International Pharmacopoeia is a model for governments to use in drafting their own pharmacopoeias.

It is noteworthy that the chairman of the United States Pharmacopoeia Committee was active in developing the International Pharmacopoeia and that the second volume was widely circulated before publication to pharmacologists and drug firms in the United States. Reports from various sources indicate that pharmacopoeial committees in different countries are being guided by the specifications recommended in the International Pharmacopoeia.

A related problem is that of advising governments on acceptable names of drugs of international importance, names that nations are willing to protect against trademark rights.

Examples have come to light where a trade-

mark has been issued to a vested interest for a name in such common use as penicillin or cortisone. Royalties, of course, are then paid to the owner of the trademark by the manufacturer and importer of the drug even though the owner did not contribute to its preparation or importation.

To prevent such vicious practice, WHO, on the advice of experts, recommends a name for a drug to each country, asking that the country examine its trademark files to be sure that the name has not been preempted. If no objection is received within 4 months, WHO recommends that the name be protected against trademark rights throughout the world.

More than 200 nonproprietary names have been recommended by the World Health Organization and accepted by the governments as the official names of these drugs. This is no little accomplishment when it is realized that such names should be readily pronounceable in three languages and should not have been preempted by another product already trademarked in any of 80 countries. This activity has been a boon to manufacturers and consumers as well as to the prescribing physicians and research scientists who can specifically identify a drug whatever its origin or labeling.

WHO also has a role in the worldwide control of addiction-producing drugs. The United Nations, by virtue of international conventions, brings illicit traffic in addiction-producing drugs under international control. On behalf of the UN, the World Health Organization determines which drugs are addiction producing and therefore subject to control. To make such determinations, the organization is aided by experts, who in turn seek advice from research laboratories.

Vaccine Field Programs

Another major area in the central technical services of the World Health Organization is stimulation of research activities which, by their very nature, must be carried on by cooperation among countries.

An example is research on the effectiveness of typhoid vaccines prepared by each of several methods. The value of these vaccines became of concern to several Western countries when ty-

phoid fever appeared in individuals who, as a result of recent vaccinations, presumably were immune.

WHO selected a country with a high typhoid attack rate and assisted the country in setting up well-controlled experiments to ascertain not only the value of vaccine but also the effectiveness of several vaccines tested.

Similarly, WHO demonstrated the effectiveness of hyperimmune serum against human rabies and the effectiveness of canine vaccine in countries where the occurrence of rabies was sufficient to make valid comparisons. Both the hyperimmune serum and the vaccine were developed in the United States, but definitive tests could not be carried out because of relatively low attack rates.

In this discussion, I have tried to bring out some of the activities of the World Health Organization that cannot be carried out by single nations but that require collaborative effort among many. Each activity substantially benefits the United States even though the results are not as readily apparent or as tangible as those of a field program aimed at the control or eradication of disease. These are the activities in which there must be collaboration by many governments. We are indeed fortunate that this collaboration can be carried on through this effective international agency, the World Health Organization, in an atmosphere of understanding of the problems of each and of looking toward common goals.

Advisory Committee on Nurse Traineeships

Twelve leaders in nursing, hospital administration, and medicine will serve on the Expert Advisory Committee for the Professional Nurse Traineeship Program.

The committee will advise the Public Health Service on the new 3-year program which provides funds to enable graduate nurses to get advanced training in supervision, administration, and teaching.

Committee members are: Dr. Robert Berson, vice president in charge of medical affairs, University of Alabama, Birmingham; Lawrence J. Bradley, director, Genesee Hospital, Rochester, N. Y.; Miss Ann Burns, chief, division of nursing, Ohio State Health Department, Columbus; Rev. John J. Flanagan, executive director, Catholic Hospital Association, St. Louis, Mo.; Miss Ada Fort, dean, School of Nursing, Emory University, Atlanta, Ga.;

Miss Frances Frazier, in charge of graduate program in public health nursing, Teachers College, Columbia University, New York City; Mrs. Lulu W. Hassenpflug, dean, School of Nursing, University of California, Los Angeles; Miss Katherine Hoffman, assistant dean, School of Nursing, University of Washington, Seattle; Miss Helen Nahm, director, department of baccalaureate and higher degree programs, National League for Nursing, New York City; Miss Agnes Ohlson, president, American Nurses' Association, and chief nursing examiner, State Examining Board, Hartford, Conn.; Miss Marguerite Pactznick, director, nursing service, Denver General Hospital, Colorado; Mrs. Margaret Filson Sheahan, director, nursing service, University of Chicago Clinics, Illinois.

Residence Laws

The many social, economic, and psychological aspects of today's State residence laws were considered at three sessions of the 83d annual forum of the National Conference of Social Work in St. Louis, May 19-25, 1956.

The following résumé of significant points in the papers on residence laws was prepared by the Tuberculosis Program of the Public Health Service.

The full papers have been published in a symposium entitled "Residence Laws: Road Block to Human Welfare" by the National Travelers Aid Association, New York City.

In the symposium, Laurin Hyde, general director of the National Travelers Aid Association, who organized and presided over the sessions, gives a brief history of residence laws. He also presents the "Statement of Principles on Residence Laws," which was adopted on March 23, 1956, by the association, leader in the current effort to amend the laws.

A Fluid Labor Force and Our Expanding Economy

Mobility has been, and perhaps will remain, the most dramatic example of what men can do if they are free to seek their own destiny in their own way, according to Robert C. Goodwin, director, Bureau of Employment Security, Department of Labor.

Except during the depression of the 1930's, each decennial census since 1890 shows that progressively larger percentages of the total population of the United States have moved from the States in which they were born. Experience during the war period proved that free people will respond to intelligent guidance.

"Free people are not moved, they move," he said. They move in response to very specific stimuli, more often than not economic, which apply to them as individuals.

Goodwin referred to the Wagner-Peyser Act of 1933, which established the present United States Employment Service and gave national recognition to the need for intelligent guidance of labor mobility. This legislation, he said, along with the Federal-State system of unemployment insurance, provided the first effective nationwide tools at the Government's disposal for improving the functioning of the labor market.

As to the future, Goodwin said that all signs point to continued mobility of our labor force. Huge metropolitan areas are increasingly

plagued by a transportation glut discouraging further industrial expansion. Huge concentrations are more vulnerable to enemy attack. Changing management concepts see greater efficiency in decentralized operations.

New means of communication make these concepts practical, he said. In addition, the development of economical power from nuclear energy may make industry possible in rural areas where it is now impossible. All this, he feels, adds up to a foreseeable greater need for the increased or at least maintained movement of people, but it may be a much more selective process than it is today.

Goodwin concluded with a challenge to those who deal with men in their social relations to see to it that they have the freedom to move without needless restraints, and that society provides them with the help they need in making the social adjustments accompanying their search.

Human Values and Personal Problems of Movement

The motives for migration, why persons and families make a change of residence, were examined by Elsie M. Rogers, executive secretary, Travelers Aid Society of Long Beach, Calif.

The complexity and variety of reasons she presented all have in common what she termed "a basic urge for security." Problems sometimes resulting from mobility are equally complex and varied, ranging from those affecting the individual to those affecting whole social groups of society. Extensive and intensive publicity about the availability of well-paid technical jobs in this or that industrial area has wide appeal. Then, the skilled technician has a buyer's market if he isn't too set on working in a specific area, but there is often no way of knowing ahead of arrival whether there is need for his skills.

Industry assumes little or no responsibility in situations where the employee's funds are exhausted before he draws his first pay. Illnesses may develop suddenly. Hostile attitudes toward newcomers or cultural groups may be encountered locally. In the agricultural field,

even though the migrant farm worker is essential to our economy if our crops are to be harvested and our people fed, legal rights depend on where one lives rather than where one works, and the migrant farmer has almost no legal rights.

The strange vagaries of our residence laws also affect the serviceman and his family who since 1940 have been moving between military posts. Though they may have been based and have lived in a given community for 1 to 6 years, they have no rights to certain benefits in that community because they do not meet State residence requirements. Another phenomenon of our new industrial age is the "company man" and his family who contribute substantially to the statistics on moving persons.

Yet, in comparison with the enormous annual migration of workers in the United States, Rogers reminded, the number who encounter problems with which they need agency help is very small. She concluded that the penalty for unawareness of these social problems arising out of our changing way of life rests with all of us. Awareness is, she said, the responsibility, and the opportunity, we have for pioneering a path toward the solution of such problems so that those who meet the challenge of a mobile labor force are not penalized.

What Happens in a State Without Residence Requirements

Peter Kasins took issue with what he termed "existing conflict in our own culture regarding the treatment of strangers"—the deep-seated disposition to extend a helping hand accompanied by a fear that helpfulness expressed in public policy may invite abuses.

Viewed in economic terms, according to the deputy commissioner for New York City affairs, New York State Department of Social Welfare, residence laws interfere with the free flow of labor and serve as a deterrent to adventure and risk-taking. Viewed in legal terms, they are in fact, if not in theory, a denial of the right of freedom of movement. Considered in social terms, they work unnecessary and often cruel hardships on people whose only fault is a willingness to take a chance.

Kasius said the time is propitious for each State to examine its own practices, to take careful note of the changing character of assistance programs, and to observe the effect of outmoded residence laws upon economic and industrial activity.

He presented certain features of this problem as seen in the experiences of one State, and particularly one city, which has had a long and troublesome history in dealing with the issue. This is the city and State of New York, and it is in New York City, as would be expected, that the greatest concentration of non-residence cases are found. Approximately 80 percent of that State's charge load is found in New York City, as compared with a 65 to 35 ratio for the total public assistance loads as between the city and upstate. But, even this disproportion should not be surprising, he said, when we consider that 13 million people move in and out of the metropolis each year. What is really amazing, he stated, is that the casualty list, as measured by relief figures, is so small.

Kasius concluded that State residence laws are reminiscent of the day when there was precious little difference between the treatment of a pauper and a criminal. He said "it is high time that we got rid of them."

The Cost to Children of Restrictive Residence Laws

The plight of children in a situation created and made worse for individuals and families by restrictive residence laws, the children who are part of the mobile family group and the children who are left behind when their parents move to another city, was described by Edna Hughes, field consultant, Child Welfare League of America.

Some intrastate laws have one residence requirement for foster home care, another for certain kinds of institutional care, and still another for medical care, with a place for State payments to fill in the gaps. Under the law and policy of one State, she said, a survey of 10 counties found 159 children who either had to be removed from foster care because their parents had lost State or county residence or their

guarantee of financial support had to be removed.

Hughes presented some common convictions about the operations of restrictive residence practices affecting children:

- Every child should be enabled to live with his own parents or a relative when they can provide a suitable home.

- Financial assistance and service to enable a child's family to nurture him should not be denied by reason of governmental boundary lines, State or local.

- Every child without parents, or whose parents cannot provide a full measure of love, care, and supervision, should receive the protection of a social agency, voluntary or governmental, without regard to the State, county, or township origins of his parents.

- A child should be returned to his parents, relatives, or the community from which he came only on the basis of a social study and a social plan which attempts to obtain for him a home and family ties.

- Respect for personality and belief in the brotherhood of man mandates us to make resources available on an equitable basis to families and children wherever they may be whenever help is needed.

In concluding she invited consideration of what the family or children's agency, public or private, can do toward solving the residence problem as it affects children. She proposed three fronts on any one or all of which she feels the challenge may be met. It is believed, she stated, that social work knowledge, skills, and experience offer to social workers and social agencies their best resources for developing methods that will be effective with this particular problem, whether it is attacked at the case, the policy, or the legislative level.

Impediment to Psychiatric and Mental Health Services

Dr. V. Terrell Davis, director of mental health, New Jersey Department of Institutions and Agencies, presented data which he feels show how restrictive residence requirements not only hamper psychiatric and mental health services, but also hamper and impede economic

progress and development of the community. He approached the question by discussing what he feels are essential features in any program for psychiatric and mental health services and by considering how these features might be restricted by residence requirements.

Davis pointed out some definite, bright signs of progress in dealing with underlying factors which may be contributing to "the symptom of restrictive residence requirements." These signs include the Interstate Mental Health Compact and an extension of Blue Cross hospital insurance coverage to include short treatment in psychiatric units of general hospitals in some areas of the country. There is also a gradual and continuing change in basic concepts of hospital admission and commitment procedures in the case of the mentally ill, with greater emphasis on procedures for voluntary admissions. Expenditures for mental health services are increasingly recognized as investments in human productivity rather than as money grudgingly spent for the care of incurables. And there is increasing legislative, community, and administrative support of the policy of treating emotionally disturbed individuals wherever they are found with the most effective and appropriate procedures available, and resolving separately the question of who is to pay.

In concluding, Davis said he believes we have definite indication that these trends, which seem to be present, may be expected to continue and develop. He said there is a growing feeling of mutual trust and respect between the professional and administrative personnel of various State and community groups. As a result, he said, these personnel have less concern about the possibility of having mentally ill patients who are nonresidents "dumped on" their facilities and resources.

Let's Face Up to Restrictive Residence Laws

"There is surely no more embarrassing anachronism in our present social structure than the body of law and practice that denies public benefits to persons whose sole disqualification is their lack of a specified period of residence in the State, county, or locality in

which they happen to find themselves," Elizabeth Wickenden, consultant and writer on public welfare, asserted.

To lend color and force to her remarks, Wickenden presented an imaginary interview between an American social worker and a visitor from Mars.

The social worker tries to explain the existing social arrangements for assisting individuals overwhelmed by economic want or other personal disaster. However, each question from the imaginary Martian places the social worker deeper and deeper into the web of legalistic barriers that close forever the doors of assistance to those not possessing the open sesame to all our social provisions: the right of legal residence. The visitor expresses great surprise at finding what he terms "village psychology" so hardy in 1956 America, especially, he says, in view of our strong nationwide economy and present role of world leadership. He says further "... it does appear that if you earthbound social workers really believe what you say about the rights of individuals, the dignity of man, the universality of social responsibility and the ability of democratic countries to shape their own social institutions to the needs of their people, you should be able to find some way to wipe out these pockets of second-class citizenship that cause you such embarrassment."

Medical Services Hampered by Restrictive Residence Requirements

The possibilities that may ensue when a tuberculosis patient is refused treatment were presented by Ruth B. Taylor, chief medical social consultant, Tuberculosis Program, Public Health Service.

The economic losses in any of these eventualities are unquestionably greater than the cost of hospitalizing the individual upon discovery of the disease, she pointed out. To some extent, however, she said, nonresidents with tuberculosis fare better than other nonresidents because the communicability of the disease is a strong factor in encouraging liberal policies. Relaxation of restrictions against these patients is, she stated, undoubtedly the result of

arduous effort on the part of public health officials. Although there is much variation throughout the country, several States have abolished (or never had) legal residence requirements for tuberculosis care, and others have ignored residence restrictions when unable to effect changes in them.

Taylor discussed a series of studies being conducted by the Tuberculosis Program, Public Health Service. These studies are designed to determine answers to specific questions about medical problems of nonresidents since data on this subject are largely nonexistent. During the 3-year interim between the first and last studies, isoniazid was introduced, and the pressures for beds have lessened in some communities. For these and other reasons, comparability and representativeness of the data cannot be claimed. However, she said, material emerging from these studies has contributed to a clarification of the nonresident problem, and current efforts are designed to determine how generally applicable the findings are to other States.

She summarized 10 major findings of the study in 22 communities in the north, southeast, midwest, and far western sections of the United States. Although these limited data allow one to draw only tentative conclusions, they have a commanding significance.

It was found that newcomers to communities do not appear to contribute disproportionately to the tuberculosis problem and nonresidents are a relatively small segment of the tuberculous population. Tuberculous nonresidents were fairly representative of the total

tuberculosis patients. They had a somewhat similar age, race, and sex distribution and had no unusual social characteristics. But they form, more or less, a cross section of the various social and economic strata. No evidence was found to support the assumption that liberalization of policies and availability of resources produced an influx of people desiring to take unfair advantage of this liberality. States from which nonresident patients migrated were widely scattered geographically. A number of other countries also were represented.

With some exceptions, citizenship did not prove to be as significant a factor in determining eligibility for tuberculosis care as residence. The overwhelming majority of nonresident patients had no established legal residence. Health officials were fairly consistent in their desire to provide needed medical services to tuberculosis patients regardless of legal residence. Sanatorium directors, welfare officials, and other investigating agents (including some professionally trained social workers) were more diverse in their reactions and frequently resisted any liberalization. The majority of the patients were hospitalized initially, but differences in philosophies were revealed in subsequent disposition.

Taylor feels the many variations in attitudes and policies toward persons with problems who do not "belong," reflect a need for an integrated and intensive program of interpretation, especially between health and welfare agencies which are presently often working at cross purposes.

Proceedings Against Four Coal-Tar Colors

A ban on four coal-tar colors used in foods is sought in proceedings begun by the Food and Drug Administration in January 1957. The colors FD&C Yellow Nos. 1-4 are involved. Nos. 3 and 4 are used extensively in coloring butter and oleomargarine.

Animal studies show that large intakes of these colors could cause injury, although no instances of harmful effects on humans have been reported. The law requires that an approved coal-tar color must be harmless regardless of the amount consumed.

The Prepayment Challenge

By W. PALMER DEARING, M.D.

BEFORE BEGINNING a discussion of the prepayment challenge from the viewpoint of a Government official, it may be well to recall that in the United States all of us are the Government. Any presentation of a Government view, therefore, must undertake to reflect the composite view of all of society, the professions, the consumers, the farmers, the businessmen, and so on. The authoritative interpretation of this view is made by Congress, which finally sets the policies, provides the funds, and reviews the performance of those of us who serve the public.

First, I propose to offer a few comments concerning the current status of health insurance and some of our hopes for the future. Then I will review some of the current Government programs which will affect and, we hope, stimulate the growth and improvement of health insurance.

I think it particularly appropriate to point out that voluntary health insurance has both fiscal and health aspects. Insofar as insurance encourages our citizens to seek medical care early, without financial deterrent, and eliminates worry over medical bills by the sick individual, its fiscal aspect contributes to health improvement. The health aspect, however, needs specific attention if the potential contributions of health insurance to health maintenance and restoration are to be fully realized. This means attention to the type, quality, and efficiency of the health services which are available through insurance. Encouragement of

comprehensive care, with proper emphasis on preventive services, and organization of service so that skilled specialty service is available when needed, but without waste, are examples of the health, as distinguished from the fiscal, aspect of insurance.

Characteristics of Prepayment Plans

Turning now to medical service plans in operation, let us note and comment on several aspects as follows:

- Insurance for care of short-term illnesses rather than for major medical expense.
- Simplicity of administration.
- Nursing and convalescent services.
- Preventive services.

First, the benefit structure of present prepayment plans is designed primarily to provide protection against the cost of short-term hospitalized illness, the most frequent cause of unpredictable medical bills.

We need now to break down the problem of medical care costs further, to look at the components of the medical bill, particularly those which involve heavy financial burdens. Urban families, for example, on the average spend only 2 cents of their medical dollar for nursing services in the home or hospital, exclusive of nursing furnished as part of hospitalization. Urban families with large medical bills of \$1,000 or more, however, spent, in 1950, 14 cents of their medical dollar for nursing services. Even these averages obscure wide individual variations. Some families spend 66 cents or more of each medical dollar for nursing services. Medical care costs to the individual differ, depending on the nature of the illness, family circumstances, entitlement to care under industrial and

Dr. Dearing is Deputy Surgeon General of the Public Health Service. His paper was one of a series on prepayment delivered at the Western Conference of Prepaid Medical Service Plans, Sun Valley, Idaho, October 12, 1956.

public programs, and other factors. The items which make up the less usual, but frequently catastrophic, medical bill need to be reexamined with a view to providing benefits more nearly in line with medical needs and services.

Despite the brief period in which major medical expense insurance has been offered, more than 5 million people now carry this type of coverage (1). Another step toward more complete protection is the extended benefits proposed by Blue Cross-Blue Shield plans. Some of these plans have experimented with limited coverage of care in convalescent homes and chronic illness hospitals, of the cost of expensive drugs and of special duty nursing. A start has been made by prepayment plans toward coverage of dental services. Progress along all these lines is essential.

To meet the needs of the buying public, we also must have an administrative base for broader health insurance offerings. Physician and hospital service plans, for example, have developed methods for joint administration of enrollments and claims. Coverage of nursing home and convalescent care has been worked out within the administrative organization of some Blue Cross plans. If it were possible to extend hospital services to provide special nursing and other auxiliary services in the home as well as in the hospital, we would have a practical base for insuring the costs of these services. This kind of arrangement would not only relieve the hospital of many nonacute long-term patients, it would also be a most valuable aid to the family physician and would reduce the costs of care.

A few hospitals now offer organized home care services. To a considerable extent, these services now are especially adapted to the needs of the indigent patient. A program similar to the home care offered by hospitals, though not necessarily as elaborate, could assist the family physician to care for his patients at home and help include these services in voluntary prepayment arrangements.

Another challenge to voluntary health insurance is the development of preventive health services. This is sound insurance practice as well as beneficial for the health of the subscribers. Well over 150 plans now offer insurance for a wide range of physician services in-

cluding diagnostic and preventive health services (2). These plans, like the Health Insurance Plan of Greater New York and the Permanente and Ross-Loos groups on the west coast, have proved it is feasible and practical to encourage the use of preventive service by insurance. Some of these plans carry on organized health education activities among their membership. Early detection and diagnosis of disease help to ease the burden of heavy medical care bills. Inclusion of diagnostic laboratory and X-ray services helps to encourage prompt attention to illness and early treatment.

Insurance carriers and the personnel who provide health services share with public health agencies the responsibility for preventive health activities. They also desire the development of health facilities and resources and their effective use for improving patient care. Some prepaid medical care plans now use the immunization, laboratory, and other services of public health departments, but many are not even aware of them. And there is also joint responsibility for health education of the public and for the development of new public health measures. We look to prepaid medical care plans for assistance in improving public health services so that they may better meet their own needs as well as those of the public generally.

Stimulating Voluntary Insurance

Now, let us turn to some of the things the Government is doing which will affect and help extend and improve voluntary medical service insurance.

One of the major health goals of the Administration is to help encourage and strengthen voluntary health insurance. Accordingly, the Administration has urged legislation which would authorize Federal reinsurance to stimulate improved coverage and expanded protection for more people. It has also sought legislation to permit small insurance carriers to pool or share their risks in developing better protection.

The Federal Government has acted in another respect to stimulate the development of sound voluntary health insurance. People have suffered from misleading advertisements, cancellation clauses buried in policies, special

riders providing for various types of exclusions, and limitations that policyholders did not understand when they paid their premiums. Action has been taken by the Federal Trade Commission during the past 2 years to correct misleading advertising. Under this stimulus, insurance companies are examining the fine print in their contracts and improving their practices from the viewpoint of the consumer.

In addition to these roles of stimulation and regulation, the Federal Government has embarked on other programs designed to improve medical services for the American people. Among these are medical research, aid to States and communities in the construction of health facilities, fellowship and training programs to relieve shortages of professional manpower, and factfinding and analysis relating to health problems, needs, and resources. In addition, the Government is working with hospital, nursing, and other groups to explore methods of reducing the costs of care. And finally, the Government is developing new methods of providing coverage for special groups such as members of the armed forces and their dependents and Federal civilian employees.

Several of the programs mentioned are new or have been recently expanded. Congressional appropriations for medical research funds were increased markedly in 1956. About half of the total national budget for medical research is financed by Federal funds, mostly distributed as grants to universities, medical schools, hospitals, and other nongovernment research institutions.

Medical research has already paid enormous dividends in reduced costs of institutional care. The savings that have accrued as a result of the discovery of antibiotics, for example, can hardly be estimated. Although it was only a short time ago, relatively few remember the exorbitant costs of care for chronic osteomyelitis, or for chronic bladder infection, or for the parietic patient. On every hand, research has paid dividends far beyond its cost.

At the same time, application of research results changes the pattern and the cost of the service which voluntary insurance undertakes to provide. Early ambulation and better control of infection shorten the period of treatment but increase the per diem cost of hospital

care as compared with the days of long convalescence with little need for expensive procedures and drugs.

The local-State-Federal program of hospital construction was broadened 2 years ago to include Federal aid in the building of chronic disease hospitals, nursing homes, diagnostic and treatment centers, and rehabilitation facilities. This program encourages flexibility in community health planning and more efficient use of manpower and resources. At the request of the Administration, this program was extended in 1956 for an additional 2 years.

Congress, also in 1956, enacted legislation to provide financial aid for the construction of medical research facilities. The Administration's recommendation for aid in the construction of medical training facilities, however, was not enacted. The Secretary of Health, Education, and Welfare has stated that the Administration will continue to press for legislation to authorize grants for teaching facilities so that the supply of badly needed research scientists and physicians may be increased.

Congress, at the recommendation of the Administration, in 1956, also authorized a program of traineeships for professional public health workers and for graduate nurses, to help prepare more nurses for supervisory and teaching positions. This legislation, in addition, authorized grants to the States for the extension of practical nurse training. The funds appropriated for the National Institutes of Health of the Public Health Service furthermore will permit a substantial expansion of fellowships and traineeships to promising young research scientists and physicians throughout the country.

Better Use of Facilities

In working toward reducing the practical barriers to medical services we need to look toward a more rational utilization of facilities and personnel, with patients cared for in the facilities appropriate to their illness. Wider use of home care, outpatient facilities, and nursing homes offers great promise, both as a method of improving the use of health manpower and facilities and of reducing the cost of care. We also need to study such innovations as the

"minimal care unit," the "hospital hotel," and the "day hospital" for the care of patients during that portion of the 24 hours when families are unable to provide care.

The Department of Health, Education, and Welfare, in September 1956, initiated a co-operative study of various types of hospital units to develop recommendations on the organization of facilities more closely related to the specific needs of patients. To assist in this task, the Secretary has appointed an advisory committee composed of physicians, hospital administrators, and nurses. Dr. Russell Nelson of Johns Hopkins University is chairman. The primary objective of the committee is to help hospitals improve care and reduce costs, particularly for patients who need only limited services. The committee, in addition, may wish to consider the problem of extension of extra-mural hospital services as a base for insurance against the costs of special nursing and other auxiliary health services in the home.

There are longstanding programs for complete care of personnel of the uniformed services and medical benefits for civilian employees injured at work. Care has also been provided for dependents of uniformed personnel but only to the extent that facilities of the particular service are available. Modern industrial health care for civilian employees, however, is provided only on a limited basis. The Administration's proposals for a voluntary health insurance plan for Federal employees, participated in by the Government as an employer, have not been enacted into law.

The most significant action in the field of health care for Government employees is the dependent care law, which will make full use of the Government's plant by opening hospitals and outpatient clinics of any uniformed service to dependents of any other. It will also remove discrimination against the estimated 800,000 dependents to whom suitable service facilities are not available by authorizing payment for hospitalization and medical care for hospitalized illness of dependents by nongovernment physicians in nongovernment hospitals.

Since 1950, the Federal Government has participated in the financing of direct vendor payments for medical care of recipients of assistance under the Federal-State welfare pro-

grams. A new program enacted in 1956 authorizes a special earmarked grant for medical care for these recipients. The program will facilitate more adequate payments to hospitals, physicians, and other personnel for services to the indigent and thus have an impact on health insurance financing.

Health Status Survey

Finally, the Federal Government has an important role in collecting information on the extent of sickness and disability and of the use of health services. These are the facts with which voluntary health insurance plans must work in expanding and extending protection. The 84th Congress provided for a continuing national survey of sickness and disability to provide comprehensive information on national health problems. In carrying out this program, it is essential that the needs of prepaid medical care plans be taken into account. The active cooperation of voluntary plans will improve the usefulness and value of the survey. Advisory committees now being set up will assure that the data will be of maximum benefit to various groups.

The national survey will yield current information on the health status of the general population. For factual data on the special groups covered under individual health insurance plans, more information should be obtained by the prepayment plans. Much of the information now gathered is not brought together. Much of what is compiled is not comparable from plan to plan. These specific data would be helpful in planning broadened coverage and in reviewing administrative organization.

Consideration should be given to an expanded research program on the economics of medical care. Establishment by the Blue Cross-Blue Shield plans of a clearinghouse for information about utilization and costs would stimulate greater uniformity in data collection and would be an important step toward improving our knowledge of the problems to be solved.

Great progress has been made and is in prospect to improve prepaid medical care and to help more American families budget against the costs of care. All of us have a stake in this job. All of us are faced with the challenge.

It will take the combined efforts of the health professions, of insurance plans, of industry and labor, and of Government to carry us closer to the goals.

Invention Reduces Fluoridation Cost

A device which will lower the cost of adding fluoride to city water supplies has been developed by two Public Health Service scientists.

The new dissolver makes it possible to use fluor spar, the most inexpensive form of fluoride, which is used in preventing tooth decay. The cost per pound of fluoride ion in fluor spar is 4.3 cents. The cost per pound of fluoride ion in other compounds used in fluoridation ranges from 41.5 cents for hydrofluosilicic acid to 12.5 cents for silicofluoride. In the larger cities, the use of fluor spar can mean substantial savings; the estimated cut in costs for Washington, D. C., for example, is about \$50,000 annually.

The apparatus was developed by F. J. Maier, sanitary engineer director, and E. Bellack, both of the Division of Dental Public Health of the Public Health Service. Six months of testing preceded release of the device.

Previously, fluor spar was impractical for use in water supplies, because it does not dissolve readily. When this compound is used in the tanklike dissolver, an alum solution is fed into the device and an agitator keeps the fluor spar in suspension to help the dissolving process. The resulting

solution is drawn off and fed into the water system.

Manufacture of the equipment by private industry is expected to begin in the near future.

Age Differential in Medical Spending

By SELMA MUSHKIN

Out-of-pocket medical care expenditures of the urban population averaged \$65 per person in 1950, a relatively small sum when considered in relation to the average city family income after taxes of about \$4,000. Unlike most other items of consumer expenditures, however, medical care costs, in the absence of insurance coverage, are neither regularly recurring annual charges nor postponable expenses like those for such hard goods as automobiles or television sets.

In a single year, a relatively small number of persons incur a large part of the Nation's private medical care bill. More than 65 percent of all urban residents spent less than \$50 for medical care in 1950. At the other extreme, 7 percent spent \$200 or more, and their expenditures accounted for 41 cents of each \$1 of the private medical care bill in cities. Only one-fourth of 1 percent of all urban residents spent \$1,000 or more for medical care, but their expenditures represented 6 cents of each \$1 of private spending for medical care in cities.

. . .

THE PATTERN of spending for medical care differs markedly among age groups. A large part of the medical expenditures for children is composed of small annual bills, whereas the major part of the medical care spending of the middle and older age groups is attributable to the large bills of a relatively few who become disabled or seriously ill.

Information on medical care expenditures was derived from a Public Health Service tabulation of schedules obtained by the Bureau of Labor Statistics in its survey of consumer ex-

penditures for 1950. In this survey, Bureau of Labor Statistics interviewers visited 15,180 dwellings in 91 cities during 1950 and 1951. As a result, complete and useful information was obtained for approximately 12,500 families. The Bureau reports that "the expenditure data from this survey appear to be the most comprehensive and reliable ever collected by the Bureau in its long experience in this field dating back to 1889" (1).

Preliminary tabulations from the Bureau of Labor Statistics survey were released in revised form in 1953 (1). Extensive analytical tabulations of the data were published for the first time in 1956 as a joint project of the Wharton School of Finance and Commerce of the University of Pennsylvania and the Bureau of Labor Statistics, financed in part by a Ford Foundation grant (2). The 1956 reports include a considerable volume of material on medical care expenditures in relation to family income, together with information on urban spending for food, clothing, housing, recreation, and other components of consumer purchases.

In the several reports on the survey, the sampling methods used to collect the information, including the selection of the 91 cities, the selection of the dwelling units in these cities, and the factors determining the size of the sample in each city, are described in detail (1, 2). The building up of nationwide urban estimates from the sample cities is also described in a published report (3). Work is still being done, by the Bureau, by the Wharton School, and by students of consumer income and expenditures, on evaluation of the distribution and aggregates of income, savings, and expenditures estimated from the survey findings (4).

Miss Mushkin is an economist in the Division of Public Health Methods, Public Health Service.

A considerable amount of the information obtained from the families on medical care costs and utilization of health services was not processed in the joint Bureau of Labor Statistics-Wharton School project. In fact, much of the detailed medical care information was not coded. Accordingly, the Public Health Service has undertaken a special study of consumer expenditures for medical care from a random subsample of the interviews. In this study, attention has been directed to (a) the composition and characteristics of the larger medical care bills, (b) the types of free medical services received by individuals in different economic circumstances, and (c) the variations in spending for medical care among different age groups. This paper presents the findings on age variations in spending.

Study Methods

In selecting the subsample, the interview schedules were stratified by the amount of medical care expenditures. The subsample included all schedules reporting expenditures of \$1,000 or more, 50 percent of those reporting \$100 to \$1,000, 20 percent of those reporting \$200 to \$400, and 10 percent of those reporting some medical care expenditures but in amounts less than \$200. To provide a basis for evaluating medical care received by public beneficiaries, such as public assistance recipients, 50 percent of the schedules reporting no medical care expenditures were also included in the subsample. In all, 2,414 consumer units and 7,639 persons were included in the subsample out of the total of 12,489 consumer units interviewed by the Bureau of Labor Statistics. A comparison of the subsample with the whole sample showed that the two corresponded very closely in the family averages for medical care spending in each of the medical expenditure intervals.

Schedules selected from the tabulation which listed schedule numbers by amount of medical care outlay were pulled from each of the city schedule files. Transcripts were then made of the information reported by the family on medical care costs and family income. Information was transcribed separately for each member of the family unit on a family sheet, and hand tabulations were made from these

family sheets. The items of medical care expense covered in the survey are given on page 119.

The figures derived from the tabulations were weighted first to adjust for the subsampling ratio and then by the regional weights developed by the Bureau of Labor Statistics for each type of city, that is, large cities, suburbs, and small cities in each of three regions of the Nation, the north, the south, and the west. The total urban population represented by the survey sample was estimated by the Bureau of Labor Statistics to be approximately 95.6 million for the year 1950.

The study findings on age differentials necessarily reflect considerable error in the reporting of information by the family respondent, in sampling, and in estimation of aggregates from tabulated data. The total dollar volume of medical care expenditures is a computed amount, estimated by applying the midpoint of each of the dollar class intervals to the estimated number of persons in each age group spending amounts within these class intervals. For the open-end expense class, \$1,000 and over, the tabulated average expense figure for the sample in each region was used instead of a midpoint.

Average Spending

Various surveys of hospital and physician services suggest a considerable variation in utilization of medical services by age. They suggest, for example, that the aged as a group use roughly 1.5 to 2 times as many days of hospitalization and 1.5 to 2.5 times as many physician services as all age groups in the civilian population (5).

There are marked differences also in out-of-pocket medical care expenditures by age (table 1). Although urban residents under 19 years of age spend half as much as the average urban resident for medical care, those 65 and over spend 28 percent more than the average.

Three out of each 10 persons living in cities are under 19 years of age, but about one-sixth of the amount spent for medical care is spent for these children. Aged persons in cities represent 8.1 percent of the urban population as

Table 1. Average out-of-pocket medical care expenditures per person, by age group, urban population, 1950

| Age group | Average annual out-of-pocket medical expenses ¹ | Percent of average expenditures of all age groups |
|---------------------|--|---|

¹ 1950 Census.

of 1950, but their medical care bills account for about 11 percent of the total (table 2).

Skewed Distribution of Spending

Averages are a peculiarly inappropriate base for evaluating consumer medical care expenditures. The skewed distribution of amounts spent by the urban population for medical care is shown in table 3. The figures reflect whatever leveling effect has developed out of coverage under voluntary health insurance since premiums are counted as part of ex-

pensitures while benefits received are excluded. A sizable proportion of medical care expenditures represents the spending of the small proportion of urban people with large medical bills.

The uneven distribution of medical care outlays is especially characteristic of the older age groups. About 8 percent of urban residents 19-44 years of age spend \$200 or more a year, but these persons spend 39 percent of the total spent by this age group. At ages 45-64, 11 percent of urban people spend \$200 or more, but their expenditures account for over half the spending for the age group. At ages 65-74 and 75 and over, 9 to 10 percent of urban people spend \$200 and over a year, and their expenditures account for 51 and 57 percent, respectively, of the medical care costs attributable to each of the age groups (tables 4 and 5).

The medical care spending pattern for children is considerably different from that for other age groups. A heavy concentration of expenditures in the large bills of a relatively small proportion of consumers has been noted repeatedly in the past as characteristic of family medical care spending and is indicated here for people 19 years of age and over. Expenditures for children, however, are largely concentrated in small annual charges. More than \$7 out of each \$10 spent for children under 6 is in amounts less than \$100, and fully one-half of the expenditure for children is in amounts less than \$50. In the age group 6-18

Table 3. Percentage distribution of persons and of total out-of-pocket medical care expenditures, by amount of medical care expenditures, urban population, 1950

| Out-of-pocket medical care expenditures | Age group | | | | | |
|---|-----------|-------|-------|-------|-------|-------------|
| | Under 6 | 6-18 | 19-44 | 45-64 | 65-74 | 75 and over |
| All urban consumers | 100.0 | 100.0 | 100.0 | 100.0 | 100.0 | 100.0 |
| None | 25.7 | 26.3 | 11.4 | 12.8 | 19.2 | 30.7 |
| \$1-\$49.99 | 61.3 | 55.8 | 46.3 | 39.1 | 41.3 | 37.2 |
| \$50-\$99.99 | 9.0 | 11.3 | 21.5 | 23.1 | 12.9 | 11.6 |
| \$100-\$199.99 | 2.9 | 1.3 | 12.5 | 13.8 | 16.7 | 11.4 |
| \$200-\$299.99 | (0.6) | 1.5 | 1.7 | 5.6 | 3.8 | (2.8) |
| \$300-\$499.99 | (0.4) | (0.6) | 2.5 | 2.8 | 4.2 | (4.1) |
| \$500 and over | (0.1) | (0.2) | 1.1 | 2.8 | (1.9) | (2.2) |

NOTE: Figures are shown in parentheses when the product of the percentages and the unweighted count of persons in the sample in the given age group is less than 10.

years, \$6 out of each \$10 spent is in amounts less than \$100. In part, the difference in the pattern of medical care expenditures by age reflects variations in sickness experience by age. The incidence of acute illness is higher among children than among older age groups, whereas the incidence of chronic illness is higher among older age groups than among children (6, 7).

Health Information Foundation Study

While the Public Health Service study of medical care costs was in process, the Health Information Foundation published its findings from a 1952-53 survey of family medical costs and voluntary health insurance (8). Differ-

ences in definition of medical care expenditures, survey design and scope, and dates of the interviews, as well as differences in age grouping make direct comparison of the two sets of findings difficult. Health Information Foundation data are for a later period and include the rural population; the Public Health Service study related exclusively to the urban population and covered 1950 expenditures. However, the similarities and variations in findings are of considerable interest and at points suggest questions which warrant further study and analysis. These two studies are the first to provide nationwide information on medical care costs by age since the 1928-33 studies of the Committee on Costs of Medical Care. The many changes that have taken place since this

Table 5. Percentage distribution of medical care expenditures of each age group by amount of medical care expenditures, urban population, 1950

| \$500 and over | (4.2) | (5.5) | 11.0 | 25.5 | (22.3) | (27.9) |

NOTE: Figures are shown in parentheses when the product of the percentages and the unweighted count of persons in the sample in the given age group is less than 10.

committee made its survey indicate considerable caution in using its data as a basis for appraising present-day medical expense patterns.

The HIF study reports \$65 as the average gross charge for medical care per person in the total civilian population for 1952-53. This is exactly the same amount as the PHS study found for the urban population in 1950.

Average gross charges for children under 6 years of age are reported at \$28 and for children 6-17 at \$38 in the HIF study. Out-of-pocket expenses for children under 6 are estimated at \$29 from the PHS study; out-of-pocket expenses for those 6-18, at \$35. There is a similar close correspondence of the figures for persons in the adult ages, except that the HIF figures suggest a larger increase in expenditures for persons 65 years of age and over than is indicated by the PHS study. The HIF

study shows a \$102 average gross charge per person 65 and over; the PHS study indicates out-of-pocket costs of \$83 per person 65 and over.

In part, the difference for the 65-and-over age group is attributable to the difference between gross charges and out-of-pocket medical care expense. Gross charges as defined in the Health Information Foundation study include amounts paid out for physician, hospital, dental, and other medical care services and for services received as insurance benefits. Out-of-pocket medical expense in the Public Health Service study does not include services received as insurance benefits but includes health insurance premiums paid. Benefits received by older people may exceed their own health insurance premiums. To the extent that this is so, health insurance may serve at present to spread the risk among age groups in the covered

Definition of Medical Care Expenditures

Medical care expense is defined in the Bureau of Labor Statistics study to include health insurance premiums paid by the family, medical expense incurred in cases of illness (other than expense covered by an insurance plan), and expenses for such items as routine physical and dental examinations and nonprescription drugs. Expenses were reported for care received during 1950 even though payments were not made until after the close of the year.

The family member interviewed was asked to report expenses for each of the following items of medical care for each family member:

Premiums. Premiums for 1950 for hospitalization, surgical, and medical service plans; premiums for 1950 for disability, health, and accident insurance.

Expenses while hospitalized. Room or ward; physician, specialist, and surgeon services; nursing services; all other charges for hospitalization (including laboratory tests, X-rays, etc.); ambulance services; combined bills (if separate items not shown).

Other medical care expenses. Physician, specialist, and surgeon services; dental care; chiropractor, faith healer, etc.; oculist, optometrist, eye

glasses, etc.; laboratory tests (other than in connection with hospitalized illness); X-rays (other than in connection with hospitalized illness); nursing care at home; prescription and nonprescription drugs and medicines; appliances and supplies; other medical care expenses.

A single expense figure was reported on some schedules for the entire family. Typically, expenditures for drugs and those premiums paid for family insurance coverage were reported in this way. For the present study, allocations were made to individual family members on the basis of the interviewer's notes when such notes indicated an appropriate basis for apportionment to individuals. In other instances, drug expenditures were apportioned equally among family members, and insurance premiums were apportioned among the family members covered in accordance with the usual practice in insurance plans of differentiating premiums for individual and for family membership without scaling premiums to family size. Premiums were allocated in equal sums among family members 18 years of age and over covered by a single premium payment.

population, and benefits added to direct personal expenditures may be larger for the older age groups than their own out-of-pocket payments, including health insurance premiums paid.

Comparison of the distribution of persons by amount of charges also indicates a general similarity in the findings of the two studies. The proportion of persons with bills of \$200 or more, for example, is 7 percent in the PIHS study, and the proportion with bills of \$195 or more is 8 percent in the IHF study. The IHF study consistently reports a larger proportion with "no charges" than the PIHS study, but again the difference may be largely the result of differences in definition of medical costs. The former study relates exclusively to medical costs paid by the family or by the insurance plan; the latter includes premiums paid for protection, with the result that persons who receive no medical services but prepay for future expenses are reported as making an out-of-pocket expenditure for medical care.

Need for Additional Information

The information on medical charges of individuals was compiled by the Health Information Foundation as a part of a study principally concerned with the distribution of costs for personal health services among families and the effect of voluntary health insurance in spreading the costs. The Bureau of Labor Statistics recorded information on medical care spending for individual family members largely to improve the reporting of total family expenditures. Although the family unit is of considerable importance in assessing the economic burdens of medical care, data on spending of individuals are needed for many purposes and by many groups such as health insurance carriers concerned with planning medical care benefit and coverage programs. In develop-

ing additional studies on the economics of medical care, it would appear desirable to plan the collection of information about the medical care spending habits of individuals and to broaden the scope of knowledge about the variations in medical care expenses by age especially in relation to differences in sickness experience.

What Public Health Nurses Like About Their Jobs

By WINIFRED KELLOGG, R.N., B.S., M.P.H.

PUBLIC HEALTH NURSES like the broad scope and variety of work that is public health nursing—the opportunity nursing gives for contact with all kinds of people, the challenge represented in the needs discovered, the satisfaction inherent in accomplishment, the stimulus to personal and professional growth.

Public health nurses leave their jobs for personal and family reasons, for more schooling and broader experience. They think of leaving their jobs when they are dissatisfied with supervision, administration, and personnel policies. Many stay, in spite of dissatisfaction, because of pension plans and for personal reasons.

Public health nurses who like their jobs are the most effective recruitment agents. Public health nurses with major dissatisfactions that are misunderstood or ignored dissipate their energies in tensions and function at a low level of efficiency. Their dissatisfaction is apparent to others. It may have an important bearing on the decreasing ratio of public health nurses to population.

These are conclusions from a recent survey of public health nursing in Michigan, described below.

Because more public health nurses are needed in Michigan, the department of public health nursing of the Michigan League for Nursing

in 1954 conducted a job satisfaction study for public health nursing similar to that for hospital, industrial, and office nursing in the Cunningham Drug Foundation survey of nursing needs and resources in Michigan. The purpose was to find the best means of recruiting nurses and of keeping active those who now are public health nurses.

The questionnaire used in the Cunningham job satisfaction survey was revised to make it applicable to public health nursing. Guidance in preparing the questionnaire was obtained from research specialists of the University of Michigan School of Public Health and from the Michigan Department of Health. Two hundred seventy-five questionnaires were sent to a random sampling of nurses employed in service agencies: one questionnaire was sent to every third nurse on the Michigan Department of Health list. One hundred sixty, more than half of the questionnaires, were returned: 126 by staff nurses, 34 by directors and supervisors.

Respondents included from 15 to 30 percent of all nurses employed in each type of agency and represented all parts of the State. They ranged in age from under 25 to over 55; in public health nursing experience, from less than 6 months to more than 30 years; in education, from no college attendance to graduate degrees; and, in public health nursing theory, from no instruction to more than 1 year.

Respondents were asked how they became aware of public health nursing vacancies, why they entered public health nursing, why they chose their jobs, what they liked and disliked about their jobs, whether they planned to

Miss Kellogg is president of the Michigan League for Nursing, Lansing. Since 1951 she has been assistant director of the Visiting Nurse Association of Detroit, and from 1937 to 1950 she was educational director of the association.

change and why, and what they planned to do if they changed. The variety of answers were studied, coded, and tabulated. Many respondents gave more than one answer to a question, and when they did not evaluate the relative importance of their answers all of those which could be coded were tabulated.

Here is a brief summary of their most frequently repeated answers, a few quotations, and some generalizations based upon their remarks.

Why public health nurses leave their jobs

Fifteen respondents had plans to leave their jobs, and an additional 20 were thinking of leaving. Nine of the thirty-five gave personal or family interests as reasons for their leaving. Six were planning to go to school. Thus, 9 percent of the total respondents were thinking of leaving their jobs for reasons which were unrelated to job satisfaction.

The remaining 20 who were thinking of leaving, or 13 percent of the total respondents, expressed great dissatisfaction regarding their jobs.

Sixteen were dissatisfied with factors coded under "supervision" or "administration." Twelve of these were staff nurses; 4 were supervisors or administrators. Six of the 16 complained of personal relationships, 5 of work pressure, 5 of supervision. One, a graduate of less than 6 months from a basic degree program, said that she was "stagnated taking care of the chronically ill." One supervisor was not sure of her ability to supervise.

Seven listed factors which coded under "personnel policies" as important to their decision to leave their jobs. Three of the seven mentioned "administration" too and are included in the 16 reported above. One respondent, in complaining of her inadequate salary said: "The satisfaction of saving humanity doesn't always fill the gaps." Salaries and reimbursement for travel were most important; vacations and leave policies were mentioned.

What public health nurses dislike

Public health nurses dislike work pressure that inhibits effectiveness. They are especially unhappy when they believe that such pressure

results from confusion, duplication of effort, a lack of administrative planning, and uncertainty regarding job responsibility. They dislike interpersonal relationships that are not based upon mutual respect for all. They dislike supervision that restricts development or fails to aid in growth. They dislike time-consuming activities which they believe do not require public health nursing skills. They dislike working where salaries and reimbursement for travel are inadequate, and where vacation and leave policies are restrictive.

Fifty-eight respondents (36 percent of the total) either gave no answer or said that there was nothing they disliked. Thirty-seven staff and 17 supervisors (34 percent of the total) listed factors related to supervision and administration as a major source of dissatisfaction.

Work pressure was most frequently mentioned. Eight staff nurses and five supervisors related this entirely to staff shortages. The supervisors indicated that there was "just no way to get the work done" even though they put in a great deal of their own personal time. Four staff nurses and three supervisors related work pressure to lack of administrative planning; to new projects being started before those under way were completed; to too many department heads and too few staff workers; to difficult relationships between individuals and divisions; to confusion and duplication; to uncertainty regarding job responsibility; and to a need for more definite written policies.

Interpersonal relationships were mentioned as a source of dissatisfaction by 19 staff nurses; supervision was a dissatisfaction for 8. Two complained because they had no supervision. Two complained because their supervisors lacked information regarding the community and made no effort to learn. One said that conferences following field supervision were delayed too long. Three complained that they could not exercise initiative or were required to follow routines too closely. Poor utilization of time was a source of dissatisfaction to three. Fatigue resulting from transporting children to clinics, dislike of truancy work, preoccupation with work that could be done by a secretary or clerk were mentioned.

Twenty-three percent of the respondents dis-

like records and reports: Thirty staff nurses and six supervisors listed preparing records and reports as the part of their job they disliked most. Seven of the thirty-six complained of other things in addition to records. Only one mentioned work pressure. Some related dislike to a lack of adequate clerical staff. The highest percentage of dislike of records was among those with the least education. There was a lower percentage of dislike among nurses who had been with the agency for more than 5 years.

Ten percent dislike environmental factors. Travel conditions, unsatisfactory office space and equipment, and inadequate community resources were mentioned. Six percent dislike personnel policies. Salaries and reimbursement for travel were first in importance, vacation and leave policies next.

What nurses like about their jobs

One hundred thirty-one individuals (82 percent of the total) said that they like the type of work they do. That is, they like working with children, with families, with community groups, with young staff and students. They like to see people get well; they like to help people stay well; they like the satisfaction of knowing they have helped. Nineteen percent mentioned factors related to supervision and administration—such things as good personal relationships, freedom to plan, opportunity to use initiative, lack of tension, pleasant working conditions, opportunity for professional growth. Fifteen percent mentioned policies regarding education, advancement, hours of work, and salaries. Only three of these individuals mentioned salaries.

Public health nurses like their jobs when they are able to see that their work is effective; when they have the guidance needed for growth and the freedom to exercise initiative in accordance with ability; when policy is clearly and flexibly applied to allow for individual and circumstantial differences; when interpersonal and interdivisional relationships are good; when lines of communication are clear; and when administration has a realistic understanding of what is involved in getting a large volume of work done.

Why nurses take specific jobs

Nurses take jobs in specific agencies located near family or friends or near educational and cultural institutions. They take jobs in specific agencies when through agency personnel or field work they learn that the agency is a "good place to work," offering opportunities for growth and job satisfaction, and that personnel policies and personal relationships are good.

Forty-seven percent of the respondents chose jobs so they could be near families, friends, or educational and cultural facilities. Thirty-four percent chose jobs because of the broad scope of the job or the type of work. Twenty-four percent were influenced by contact with public health nursing personnel and others who knew about the work. Twenty-three percent gave reasons which coded under "personnel policies." Sick leave policies were mentioned several times.

Why they take public health jobs

Forty-nine percent of the respondents said in a variety of ways that they entered the field of public health because they were interested in people, liked children, liked working with families, liked school work, or liked community work. Their replies were coded under "broad scope of the work." Contact with public health nurses and others who knew about the work influenced the decision of 42 percent of the respondents. Experiences during basic nursing and field work were frequently mentioned. Personnel policies were important to 25 percent; specifically mentioned were hours of work and policies regarding education, advancement, and salaries. Job exploration was mentioned by 18 percent of the respondents.

How nurses learned about vacancies

Nurses enter the field of public health when through contact with public health nurses and others who know about the work, they become aware of the opportunities and challenges it presents.

Two-thirds of the respondents learned about their jobs from staff or board members, relatives, friends, physicians, or field work in the

agency. Very few learned about their jobs from such sources as professional journals and employment agencies.

Plans about changing jobs

Of the 29 nurses who were thinking of leaving their jobs, exclusive of those who were going to school, 1 will probably not leave, 7 will take other public health nursing jobs in Michigan, 9 will take public health nursing jobs in other States, 5 will enter a different field of nursing, and 4 will leave nursing altogether.

The four who said they would leave nursing were staff nurses, and all were married. Two were leaving for personal reasons and two because of work pressure, personal relationships, and the wrong kind of supervision.

The percentage of respondents who were planning to leave their jobs was highest in those under 25 and lowest in those over 55.

Unfinished business

Nurses in all types of agencies expressed major dissatisfaction regarding certain aspects of their jobs. There is no possible way to judge the validity of respondents' complaints. Administrative and supervisory practice may not be as bad as some think, but as long as that thought remains, the agency and each individual in it has a problem. Certain it is, there is room for improvement. The administrator, supervisor, or staff nurse who disclaims responsibility in the situation is apt to be the very one who most needs to take it seriously. Dissatisfaction when properly understood and utilized may serve as stimulus to improvement.

Many studies have been made in Michigan and throughout the country. Too frequently, reports are compiled and filed for future discard. We hope to do better with our job satisfaction study. Though we acquired little new information, we do believe that our findings are significant, and we intend to use them as a stimulus to improvement. We believe they have value too for other States.

A brief mimeographed report of the study, which is essentially the same as the foregoing findings, was printed in April 1955 and distributed to nursing agencies by the public health

nursing section of the Michigan Department of Health. Accompanying the report was a list of questions to consider in analyzing their own situation.

Questions for consideration

The list of questions distributed with the job satisfaction report is reproduced below:

1. Which of the findings reported here are true for your agency?

2. Are staff and board members aware of their potential strength as recruitment agents? How can such awareness be stimulated and utilized?

3. Do field staff and board members have access to application forms, personnel policy outlines, and promotional materials? Do they make use of them?

4. Are board and committee members and others in the community aware of the tremendously satisfying aspects of the public health nursing job? Can these people be made aware of this factor so that they will talk of it among their friends and relatives, some of whom may happen to be nurses?

5. Are staff members utilizing the educational and cultural facilities of the community in their own personal development? If such facilities are inadequate, could more adequate resources be created and developed?

6. Do all staff members understand supervisory and administrative processes? Are communication lines clear? Do the field staff, supervisors, and junior administrators have some freedom to make professional decisions and exercise initiative?

7. When administrators decide to embark upon a new program, do they either add staff or cut the established program to make time for the new? Do they consider clerical as well as other needs?

8. How can specialized division heads keep themselves and each other aware of the pressures created by their demands upon generalized supervisors and staff?

9. What can be done to help nurses with records and reports? Is adequate clerical help provided? If full-time clerical help is either not needed or not available, has an attempt been made to find part-time workers? Do nurses

have adequate space and a quiet time for doing clerical work? Are they given an adequate introduction to recordkeeping? Do they need courses in rhetoric? Is information requested that is not essential? Are field nurses aware of uses made of statistical information collected?

10. Are personnel policies at least up to the minimum standard recommended by the profes-

sional nurses' association in your community? How satisfactory are the policies about salaries, mileage rates for the use of personal cars, working hours, vacation, and leave? Can an employee who has served for many years get a 1- to 3-month leave of absence, other than for schooling, without loss of seniority or civil service status?

Program for Evaluating Heart Disease Drugs

A grant of \$575,000 to evaluate the effectiveness of drugs used in heart disease treatment was awarded Dr. Alan E. Treloar, director of research of the American Hospital Association.

The research grant, the largest of its kind ever made by the National Heart Institute of the Public Health Service, will finance a nationwide program coordinating the work of a number of research teams, as yet to be selected.

The projected large-scale study involves a testing program to determine the most effective drugs, or combinations of drugs, and dosages among the many new forms of treatment developing in the heart field. Initial emphasis will be on hypertension.

Dr. Treloar and the American Hospital Association envision the formation of an advisory board to set up the program's guiding principles and to make broad policy decisions. The board will be composed of eminent medical research workers and clinicians; it is expected to include a representative of an appropriate committee of the American Medical Association and also of the American Heart Association.

A central staff located in Chicago will include a clinician and a biostatistician who will coordinate project activities and supply administrative and biostatistical services for investigators. Each hospital and clinical research laboratory collaborating in the program will provide a representative for a technical committee. This group will serve as a means for constant communication between the research teams and will determine details of procedure.

The San Juan Basin Plan

By GEORGE MOORE, M.D., M.P.H.

IN THE EVENT of a national emergency from enemy attack, the small cities, towns, and villages of America will save the populations of many of the larger industrial cities. This statement cannot be questioned since the primary targets in the United States include most large cities with their factories and congested populations. How can the small cities and towns in rural areas save their urban neighbors? The San Juan Basin of Colorado has attempted to provide an answer.

Some 33,000 people live in the San Juan Basin, a four-corner, 12,000-square-mile area flanked by the high mountain ranges of the Rockies. The basin is central to Albuquerque

in New Mexico, to Phoenix in Arizona, to Salt Lake City in Utah, and to Denver and Pueblo in Colorado. Distances to these cities range from 200 to 500 miles. Most east-west and north-south highways in this region of the southwest converge on Durango and Cortez, Colo., the basin's largest communities. Durango has a population of 12,000, Cortez, 5,000.

In the event of enemy attack, no target in the basin would be worthy of enemy bombs, but dangers do exist. Radioactive fallout from the bombed cities may drift over the basin. Enemy saboteurs may plot destruction of vital installations. Thousands of evacuees may seek refuge in our homes and hospitals.

The danger of radioactive fallout has been met by establishing in Durango, at a cost of about \$1,000, a detection station that houses a Staplex single-volume air sampler. Manned by a team of health department personnel, the instrument is capable of detecting minute amounts of radioactivity in the air before the danger becomes serious, thus providing hours of warning. It operates on 110-volt current or by a generator.

A weather bureau official computes the fallout patterns and relays his findings to our radio

Dr. Moore, director of the San Juan Basin Health Unit, Durango, Colo., is one of three physicians appointed by the San Juan Basin Medical Society to plan for medical care in an areawide emergency. An account of Dr. Moore's experience as chief public health officer, United States Operations Mission to Nepal, 1952 to 1954, appeared in the April 1954 issue of Public Health Reports, p. 340.

station for Conelrad broadcasts on 640 and 1240 AM frequencies. If, after an attack, the team should find that fallout is a serious hazard, civil defense officials could confidently call for withdrawal toward a safer area. Mass evacuation of the basin's families can thus be a leisurely and simple procedure.

As to the second danger, we can expect that one-way bombers after their bombing runs from the north might land on the flat mesas and prairies of central and southwest States. We can also reasonably expect that airmen conversant with American customs and perhaps trained in sabotage will enter cities and towns unnoticed and mingle with the populace. Their job would be to foment panic, to set fires in forests and lumberyards, to destroy

bridges, powerplants, and oil dumps, and to contaminate water and food supplies with chemical and bacteriological agents.

A third problem, fraught with danger too, is the extent of our preparedness to receive and care for evacuees. If a city such as Albuquerque with a population of 160,000 has at least 3 hours' warning, it is expected that about 150,000 persons could be evacuated. Possibly 20,000 or more refugees will find their way northward across the desert to the mountainous San Juan Basin.

Many of these evacuees, hungry, desperate, sick, and afraid, might conceivably ransack and loot stores, gasoline pumps, and food warehouses, leaving nothing for evacuees or residents alike. And without further food and

Their job would be to foment panic, to set fires in forests and lumberyards, to destroy

bridges, powerplants, and oil dumps, and to contaminate water and food supplies with chemical and bacteriological agents.

A third problem, fraught with danger too, is the extent of our preparedness to receive and care for evacuees. If a city such as Albuquerque with a population of 160,000 has at least 3 hours' warning, it is expected that about 150,000 persons could be evacuated. Possibly 20,000 or more refugees will find their way northward across the desert to the mountainous San Juan Basin.

Many of these evacuees, hungry, desperate, sick, and afraid, might conceivably ransack and loot stores, gasoline pumps, and food warehouses, leaving nothing for evacuees or residents alike. And without further food and

for Small City Survival

stores for 3 weeks or more, the basin's inhabitants would themselves become victims of war. Therefore, an orderly reception of evacuees is necessary to insure help and rapid recovery for all.

The Fortress City

The survival plan is for Durango to consider itself a fortress in time of attack. At the flash of national alert, the city will go under civil defense authority, similar to martial law in many respects. All emergency teams will proceed to their stations.

Main highways leading into Durango will be barricaded with bulldozers and trucks, leaving detour routes around the city open for outside traffic as needed. All traffic within the city, except emergency and official vehicles, will be stopped. Places of business and service stations will be closed. Armed guards will be posted in front of food stores to prevent runs on supplies. School children will be sent home immediately. People will be warned to stay in their homes.

Thus, the city will be ready for attack, teams will be at their posts, and residents and workers will be at home waiting for Conelrad reports on their radios. In this period of waiting the public will ready their cars, fill tanks with stored supplies of gasoline, draw off water for storage, and prepare baskets of food. Conelrad in cooperation with the detection station will advise of fallout from bombed areas. If mass evacuation of the city is necessary, Conelrad will describe the routes to designated rendezvous points.

Reception of Evacuees

When the first evacuees arrive at Durango, they will be met at the roadblocks by the traffic control teams. If they prefer to detour the city, they will be offered a cup of coffee and a sandwich by a welfare team and then directed to follow the markers. Gas stations at each barricade will ration a few gallons of fuel, if needed, to each vehicle as long as the gasoline lasts.

For the 20,000 evacuees who prefer to stay in Durango, a different procedure is planned.

These individuals will be met at the barricades by monitoring teams who, with geiger counters and ionization chambers, will check for radioactive fallout dust. Vehicles found to be radioactive will be either left outside the barricade or motioned on toward the detour, as the occupants prefer. Vehicles found free from contamination are then screened by the police for saboteurs. Luggage and identification will be checked thoroughly before either a vehicle or person is permitted to pass the barrier. Arrangements have been made for the care of pets.

Each barricade will have a mobile first aid team led by a physician. The team will send injured and ill evacuees, by ambulance or truck, to one of three first aid centers temporarily established in the Durango public schools. The injured and sick will be treated at the first aid stations and then either transferred to a hospital or released to one of five registration centers. The healthy evacuees will be directed to a wide parking expanse where traffic teams will park the cars in an orderly fashion. Radios at the barricade will keep the teams informed of possible new dangers.

"Saboteur" found on public street by Durango police during simulated alert, July 1956.

At the parking lot, the evacuees, carrying their luggage, will board school buses waiting to shuttle them to the registration centers. The centers are to be located in public buildings central to each of five main sections in the city. They will be manned by volunteers and welfare officials. After registration, evacuees will be sent on foot, in company with boy scouts or uniformed guides, to their assigned quarters in the homes of residents. A list of available rooms is ready in anticipation of this maneuver.

In the interim, the fire department will have been waiting for emergency calls, and the police department will have stationed guards at bridges, gas depots, water works, and other vulnerable sites. Factories will have assigned men to guard industrial targets. The relative absence of street traffic will simplify the job of safeguarding people, homes, and key targets. Likewise, the detection of looters and saboteurs will be less difficult.

The next morning should see Durango intact with all evacuees received and placed. The care and conservation of what is left then begins.

Realistic Planning

A full count of evacuees and an inventory of food, clothing, gasoline, and medical supplies will determine how the city will live for the next few weeks. Health officials will check water and food for possible contamination and will try to maintain near normal services. Twice a day, volunteers and welfare and health personnel will set up food lines at the fairgrounds and at large restaurants.

For supplementary needs the granges have accumulated stores of extra supplies of canned food, fruit, potatoes, and gasoline. These will be rationed as needed. At any time, we could supply 25,000 to 30,000 pounds of milk, 25,000 head of beef cattle, 60,000 sheep, and 1,000 hogs. Flour, pinto beans, and grain are abundant. Food, therefore, should not be a problem.

If the watershed becomes contaminated with fallout, we would have enough stored water, once the reservoir is covered as planned for 1957, to last evacuees and residents 3 weeks. Water supplies have been tremendously improved this year over last by the addition of

Sheriff and civil defense aide find "bomb" under oil tank in Durango suburban area.

a new filter plant in Durango. Water during most of the year is plentiful. Most farms have wells, and water will be transported to the cities as needed. Our fast-flowing streams could in warm weather decontaminate most of the watershed within a week. Sewerage, though inadequate, also has top priority in city budgeting.

The police and firemen in Durango have been trained by former Army servicemen in many types of counter sabotage. The police and fire departments held an impressive operation alert in July 1956 together with civil defense teams, health department personnel, and amateur radio operators. The exercise simulated a realistic emergency complete with enemy agents plotting to contaminate water, incendiary fires ignited in army-type smoke pots, and time bombs planted at strategic sites (see pictures).

During an alert, auxiliary police will patrol the filter plant and reservoir, and our sanitation staff will stand by for any emergency. Continuous check will be made on the water for turbidity, changes in pH, presence of bacteriological agents, and deposits of radioactive fallout if it is a problem. The small laboratory of our health department and the technician in charge are well equipped and well qualified to make bacteriological examinations. We hope to acquire a millipore filter soon.

All of the health department staff have received special training in civil defense through courses in Denver and in Washington. They in turn have helped to train civil defense work-

ers in Durango (see program). The monitoring teams have been trained in food and water decontamination. The fluorescent antibody and phage tests for rapid bacteriological diagnosis as well as complete kits for CW (chemical warfare) sampling will be added to our program as soon as these materials are released. At present, public health defense against BW and CW attacks is not particularly effective until the specific agent is determined and after people are already sick and dying.

The San Juan Basin Health Unit now has a full year's determination of background counts on radioactive fallout. The Colorado State Health Department gave valuable assistance in calibrating the air sampler and in training health personnel in radiation detection. The weather bureau official who will chart and relay fallout reports was sent to the Sandia Corporation in New Mexico for special training.

Natural and Wartime Disasters

The survival plan will utilize every available inch of space in the hospitals as well as in auxiliary buildings. The only hospitals in the basin are the two hospitals in Durango and the hospital in Cortez. Altogether we count on having 300 hospital beds, 25 physicians, 6 dentists, 4 veterinarians, 185 first aid workers, and about 150 nurses and aides. All available nurses have been listed. If disaster strikes a nearby city, a team of 6 physicians with nurses and helpers and supplies is ready for call.

A move has been made to bring Federal Civil Defense Administration stockpiling to the basin because of the remoteness of the stockpiles in Texas and Utah and at Greeley, Colo. All hospitals are stockpiling medical supplies and rotating perishable items. Eventually, their stockpiles will hold a year's supply in advance.

Vaccines and serums are not being stockpiled to any great extent because it is not in our present plan to offer immunizations to the public at large. The health unit has been attempting to provide mass immunization through school programs. Immunization levels among school children are well over 85 percent for smallpox and diphtheria-pertussis-tetanus.

Civil Defense Training Course

San Juan Basin Health Unit

First Day

Strategic briefing of civil defense.

Effects of modern weapons. Films "Let's Face It" and "Operation Ivy."

Nuclear weapons and radiation detection instruments. Film "A Is For Atom."

Evaluation of radioactive fallout hazard.

Biomedical effects of radiation.

Chemical warfare.

Bacteriological warfare.

Films "Flash of Darkness" and "Target You."

Evening

Films "Atomic Attack" and "Frontline of Freedom."

Second Day

Civil defense analysis.

Attack warning. Film "Conelrad."

Civil defense organization.

Organization of health services, casualty care, health and medical supply program, and the improvised hospital.

Durango as a typical support area, urban analysis.

Evacuation, shelters, and cover. Films "Escape Route" and "Operation Welcome."

Rescue training. Film "Trapped."

Registration and warden services.

Police and traffic services.

In addition, the Indians in the basin are now protected with typhoid-paratyphoid vaccine.

We have tried to be realistic in planning for various types of casualties. In addition to screening evacuees for communicable disease, we have made specific provisions for isolation of disease suspects at first aid stations, for the use of churches and churchmen to help alleviate hysteria and panic, and for hospitals to set aside wards for radiation victims. Evacuees with burns, fractures, amputations, and other serious conditions are not expected in great numbers because of the basin's distance from target areas. They may be sent here later, however.

Of course, no one knows how many evacuees the basin might receive, but, for our planning, a total of 20,000 has seemed a practical number to assume. Durango, with new discoveries of oil, gas, and uranium, has become a boom town since the war. Housing is at a premium, and most new homes are ranch style and small. We would have trouble accepting more than 20,000 new people, but if we had no choice, we would use barns, rodeo facilities, and all available public buildings.

Considerable interest has been expressed in our plan. A mutual aid pact is being drawn up with Farmington, N. Mex., the first large city south on the road to Albuquerque. Farmington will detour evacuees to us as we will to them if cities to the north of Durango are bombed. Other cities in Colorado and New Mexico and even in South Dakota have shown interest in organizing similar programs. It

has been obvious that the public is worried about the future and will work enthusiastically if we lead the way and provide hope.

The basin also has an alternative emergency plan that covers the natural disasters any community might experience from train wrecks, fires, collapsed buildings, and flood. Not more than 50 casualties are expected from any one isolated incident. These we will care for by using the maximum available beds in the basin's hospitals. The hospitals are prepared, as needed, to reroute their patients and to provide morgues and extra dispensary space. Physicians have specific assignments.

Now that all phases of both plans are complete, we trust that the basin will be ready for whatever comes, natural and war disasters alike.

idea

The Personal Touch

Though approximately 400 persons receive postgraduate training in public health every year, the profession is probably losing between 600 and 700. States fortunate enough to have a reasonable number of public health workers have usually obtained the greater proportion from adjoining areas.

Our replacement needs and the additional workers needed to meet the demands of a growing population have to be viewed realistically in the light of the decreased supply of young people, brought on by the reduced birth rate from 1930 to 1941, and of the many inducements that are currently offered to them.

Industry's profits at the moment are of such magnitude in relation to

the tax structure that industries can afford to pay salaries to professional personnel for beginning employment in ranges that industries themselves recognize are greater than the employee is actually worth.

Training for public health work, usually provided from public funds because it primarily benefits the employer, has declined appreciably because of cuts in Federal grant funds. Some States have been reluctant to finance training or have been unable by law to do so. Thus, the cost of preparation is devolving upon the individuals themselves even though financial compensation, when employed, does not compare favorably with that of industry.

Since competition for personnel is so keen, I would like to suggest that there is a common need for bringing to seventh, eighth, and ninth graders some concept of the many interesting things that can be done in public health work. I would encourage maximum sensitization of this

group through whatever channels you can use to reach them. Perhaps too few of us have thought about the influence we could have by working actively in such groups as the Boy Scouts and Girl Scouts and the Hi-Y and 4-H clubs.

The most effective recruitment program I have seen for getting young ladies into a nursing school was one in which each student was given the responsibility for seeking out some worthy successor from her former high school and giving her a pledge pin.

Our recruitment programs must be personalized if they are to be effective.

—**HARALD M. GRANING, M.D.**, regional medical director with the Public Health Service, Region 5, Chicago, in a speech at the annual meeting of the Middle States Public Health Association, Columbus, Ohio, April 30, 1956.

technical publications

Diabetes Program Guide

PHS Publication No. 566. 72 pages, 45 cents.

State and local workers in diabetes control activities will find in this compact guide a complete presentation of the principles and procedures of community diabetes programs, starting with community resources and proceeding through prevention to case finding, education, evaluation, and research.

Emphasis is placed on testing, with statistical and laboratory procedures treated in some detail.

Criteria of success in diabetes programs are stated as: finding unrecognized diabetics and following them to diagnosis and treatment; helping prevent or correct obesity; helping diabetics control their condition under medical supervision; promoting the understanding of diabetes through individual and group education; and mobilizing community resources.

Included are forms and form letters, seven pages of references, and a detailed section on the cost of screening, with data on both laboratory costs and personnel.

Your Child from One to Six

Children's Bureau Publication No. 30. Revised 1956. 110 pages; illustrated. 20 cents.

This revised bulletin for parents emphasizes the mental and emotional development of children from infancy to school age.

The problem of television viewing is discussed for the first time. Other new sections point out how a child can learn to do without its mother, how to prepare a child for hospitalization, and what to tell a child who asks about death.

A comprehensive medical section tells how to handle emergencies, how

to care for a sick child, and how to prevent and recognize illness. Also provided is a complete immunization plan for children from one month of age throughout childhood.

Public Health

Merit Badge Series No. 3251. 1956. Boy Scouts of America. 66 pages; illustrated. 25 cents.

A new version of this pamphlet has been prepared in association with the Public Health Service. Designed to help Boy Scouts qualify for a merit badge, it is also an elementary introduction to basic concepts and programs of the public health profession.

Sources of Morbidity Data. Listing Number 4. 1956

PHS Publication No. 564. 1956. 74 pages.

The fourth listing of projects in the files of the Clearinghouse on Current Morbidity Statistics Projects contains descriptions of 102 projects, supplementing the 477 described in Listings Nos. 1, 2, and 3 (PHS Publications Nos. 332, 399, and 459).

There are three indexes: the projects by type of data collection; the organizations and institutions participating in the projects, by State; and the principal investigators. Also included is a section of supplementary notes representing a systematic followup on projects in the previous listings that were in progress when their descriptions were received by the clearinghouse.

Because the listings of the clearinghouse are published primarily for the use of actual and potential contributors, the number of bound copies available for other distribu-

tion is limited. Tear sheets for all projects are on file, however, and these will be mailed free of charge to persons inquiring about studies of a particular type.

Federal Support for Science Students in Higher Education, 1954

National Science Foundation Publication No. 56-18. 33 pages. 39 cents.

Designed to assist in evaluating proposals for federally financed scholarships in the sciences, this report provides information on present Federal aid to college and university science students.

It shows how much of the expenditure (in the form of fellowships or otherwise) in each program went to students in the various scientific disciplines; how many career science students were assisted; which Federal agencies were involved; how the various forms of financial aid were distributed among those studying in scientific fields; and, how, among the fields of study at graduate level, the federally aided group of science students compares with the nationwide graduate student body in the sciences.

Data on students in nonscience fields are included in the aggregate only for comparison.

This section carries announcements of all new Public Health Service publications and of selected new publications on health topics prepared by other Federal Government agencies.

Publications for which prices are quoted are for sale by the Superintendent of Documents, U. S. Government Printing Office, Washington 25, D. C. Orders should be accompanied by cash, check, or money order and should fully identify the publication. Public Health Service publications which do not carry price quotations, as well as single sample copies of those for which prices are shown, can be obtained without charge from the Public Inquiries Branch, Public Health Service, Washington 25, D. C.

The Public Health Service does not supply publications issued by other agencies.

Film an Educational Aid In New Mexico's Venereal Disease Program

By BERNARD F. ROSENBLUM, M.D., M.P.H.,
and WILSON A. CORCORAN, B.A.

NEW MEXICO, in 1955, ranked sixth in reported cases of syphilis. For the young age groups, those aged 15 to 25 years, the significance of the venereal disease problem in the State is shown by the figures for that year and for 1954.

For 1955, in the age group 15 to 25, there were 212 cases of syphilis, 797 of gonorrhea, and 9 of chancroid, a total of 1,018 cases of venereal disease of all types. This was 40 percent of the total of 2,609 for the State. For 1954, the total was 2,533 cases, of which 1,108, or 44 percent, were in the group aged 15 to 25 years.

When the film, "The Invader," was shown to the staff of the New Mexico Department of Public Health, it was agreed that here was an excellent film for use in our venereal disease educational program. It was particularly suited to the age groups we wished to reach. The film was previewed at different showings by the New Mexico Parent-Teacher Association officials, the Catholic Archdiocese, and the Ministerial Alliance. All were impressed, and gave their approval and endorsement for "The Invader" to be shown to any and all groups, including public, parochial, and private schools.

A letter was sent to all local school and parent-teacher association officials telling them of the venereal disease conditions in the

Dr. Rosenblum and Mr. Corcoran of the Public Health Service Venereal Disease Program are with the New Mexico Department of Public Health, Santa Fe, N. Mex. Dr. Rosenblum is venereal disease control officer and director of the division of preventive medicine. Mr. Corcoran, a health program representative, is also assigned to that division.

This paper was presented at the First International Symposium on Venereal Diseases and the Treponematoses, Washington, D. C., May 28-June 1, 1956.

State and of the proposal to use the film, "The Invader," as an integral part of the health department's approach to the problem. The letter included a short paragraph about the contents of the film and stated that it had been previewed and unanimously approved by the State Parent-Teacher Association, the Catholic Archdiocese, and the Ministerial Alliance. It was suggested that the local parent-teacher association preview the film one evening and present it to the students the following day. A mimeographed list of the 20 questions most commonly asked about venereal disease was enclosed, for presentation to the students prior to their viewing the film. The questions were in a "true or false" form, and the student was not required to sign his name but to give only his age, sex, and grade in school. The letter requested dates and alternate dates of the parent-teacher association meetings.

Response was immediate and overwhelming. The health department was swamped with requests for the film. With only one print on loan from the Venereal Disease Program of the Public Health Service, we were in need of additional prints if we were to carry out the educational program, including the showings of "The Invader," within a 12-month period. One print was purchased, and we prevailed on the Regional Office of the Public Health Service in Dallas, Tex., to lend us another print. With three prints to be divided among a field staff of five, stationed from 200 to 300 miles apart, and the home staff of two, the three films had to be scheduled to arrive at the right time and the right place for a 2-day stay and then be sent to the next showing. Coordinating the logistics on these procedures required the combined efforts of the home and field staffs. Because mail service is often delayed in New Mexico, the prints were sent by public interstate buses. This means of transportation is widely used in New Mexico and offers more frequent and better service to remote areas than do the railroads in transporting mail and freight.

At parent-teacher association meetings, "The Invader" was presented by a member of the health department staff, usually one of the trained venereal disease investigator-interviewers or, rarely, by a public health nurse. The usual procedure was to give a 5-minute

"The Invader"

"The Invader" is a film history of syphilis from the Renaissance to the present day. The pictures and text tell of the 400-year search of scientists for a cure for syphilis, of the discovery of penicillin by Fleming in 1928, and of Mahoney's work with penicillin which resulted in the announcement in 1943 that a cure for syphilis had been found. The film also gives an account of the fight for open discussion of syphilis so that syphilitics can be reached and the "chain of infection" broken.

The informative Film Guide for Teachers and Discussion Leaders issued by the division of instruction of the Georgia Department of Education states that the film "leaves the viewer with the feeling that everyone has a part in helping to conquer syphilis" and that "the surest control of syphilis comes from the integrity within that makes a man or woman live by decent values."

introduction, usually confined to the venereal disease situation in the State, with a few words about the length of the film. The audience was told that a question period would follow the showing of the film.

The following day, when the program was presented to students, usually boys and girls together, the introduction contained the statement that syphilis is a communicable disease and that the program was being presented on that basis and not on the basis of sex education. The students were told that a question and answer period would follow the film and also that the correct answers to the 20 questions distributed earlier would be given. These question lists, which were preferably completed a day or two prior to the showing of the film, were collected by the person showing the film and later were forwarded to the State health department for tabulation. A program has yet to be completed during which the students did not ask questions, such as, "Is there any vaccine for immunity to syphilis?" and, "Can syphilis be inherited?" Almost everyone expressed the opinion that they had learned many things they had not known before, and that they had enjoyed the film.

Some "do's" and "don'ts" may be of value in presenting this film. In making final schedules, make sure that the time does not conflict with a local basketball game, baseball game, or other event, or the program will be presented to an empty hall. When the film is to be shown to several schools in the same community, a local movie theater may be used, thereby saving precious time and personnel. It is wise to carry a projector and a screen and an extra 50 feet of extension cord. Frequently, the projector provided by the school or organization has something wrong with it, and unless a workable projector is on hand, the program will be a failure. Care should be taken to rewind the film after each showing. It is embarrassing to begin a new showing of the film and have to stop and rewind it, thus losing the attention of the audience. When making arrangements to ship the film to another location, the task of transportation should be delegated to a responsible person or the film may be mislaid and delayed, disrupting the schedule.

Through these methods and efforts "The Invader" was shown to 68,229 persons during September 1955-June 1956. The film was seen by the students and faculty of public, parochial, and private junior and senior high schools; civic groups, such as PTA's and miscellaneous clubs; and military personnel, as follows:

| | High schools | Civic groups | Military personnel |
|------------------------|--------------|--------------|--------------------|
| Attendance..... | 33,791 | 19,500 | 14,938 |
| Number of groups..... | 129 | 207 | 5 |
| Number of showings.... | 273 | 207 | 54 |

The following suggestions may help in planning future programs:

1. The film should be prepared with commentaries in several languages. A Spanish commentary would be useful in New Mexico.

2. If the film could be shortened it could be used advantageously for television showing. It is very difficult and expensive to get television time, and "The Invader" runs 37 minutes, making it awkward to fit the pattern of 30-minute TV programs. A 20-minute showing, with an 8-minute discussion, would make a 30-minute program with 2 minutes for the announcer.

Because of its success in New Mexico, we recommend showing "The Invader" as an integral part of a venereal disease education program.

Contributions of Premarital and Prenatal Blood Testing in Syphilis Control

By HAROLD J. MAGNUSON, M.D., JAMES F. DONOHUE, M.P.H., JOHANNES STUART, Ph.D.,
and GERALDINE A. GLEESON, A.B.

MUCH OF THE PROGRESS in syphilis control during recent years has been accomplished through the cooperative efforts of the national venereal disease control program, State and local health departments, and various private agencies. The control measures and techniques used by these health agencies form such a closely integrated system that it is difficult to break down the contributions of certain components or to evaluate the efficiency of specific control measures. However, in this report two segments of the program, namely, premarital and prenatal blood-testing legislation, have been isolated, and an attempt has been made to measure the specific accomplishments of required blood testing.

Aside from the case-finding aspects of required blood-testing programs, the primary purpose of premarital and prenatal blood testing is to preserve the health and welfare of the family unit by preventing the transmission of

syphilis to marital partners and by protecting unborn children from infection with congenital syphilis. Such blood testing also has its educative values.

One of the most immediate results of effective premarital and prenatal blood-testing legislation should be reduction of infant mortality due to syphilis. But since there has been a general downward trend in infant mortality from syphilis during the past 20 years, it is difficult to determine by observation alone whether this reduction in rates would have occurred regardless of blood-testing legislation, or whether there is a definite relationship between the two factors.

In an attempt to distinguish between the reduction in infant mortality due to blood-testing legislation and the general downward trend in infant mortality, composite rates per 1,000 live births for infant deaths due to syphilis were computed for States having prenatal blood-testing laws during 3 years prior to the year the law became effective. Assuming these three yearly rates to be representative of the general trend of infant mortality due to syphilis immediately preceding the passage of the law, a straight line trend ($a+bx$) was fitted to these rates and then extended through 5 years following prenatal legislation. Confidence limits at the 1 percent level of significance were set up about this extended line to allow for chance variation. The actual observed rates were plotted for the 5 years.

Figure 1 shows that the observed infant mortality rates for all years are significantly lower

Mr. Donohue and Dr. Stuart are chief statistician and program management officer, respectively, Venereal Disease Program, Public Health Service. Dr. Magnuson, chief of the Occupational Health Program, and Mrs. Gleeson, a statistician with the Air Pollution Medical Program, were formerly with the Venereal Disease Program, Dr. Magnuson as chief of the Operational Research Section and Mrs. Gleeson as a statistician.

This paper was presented at the Third Biennial Planning Conference of the Association of State and Territorial Health Directors, Washington, D. C., May 25, 1956.

Figure 1. Composite rate of infant mortality due to syphilis in 42 States before and after enactment of prenatal blood-testing law.

than the expected trend based on rates prior to blood-testing legislation. As a specific contribution to syphilis control, it is estimated that through the effectiveness of prenatal blood testing 1,000 infant deaths from syphilis were prevented in 42 States during the first 5 years following enactment of the law. Since 30 of the 42 States with prenatal blood-testing laws had enacted these laws during 1943, or earlier, the interval represented in the 5-year period is largely coincident with the war years and the immediate postwar years. This reduction in infant mortality due to syphilis becomes even more remarkable in view of the fact that it was accomplished during a period when infectious syphilis case rates among civilians were at a peak and before penicillin became available for civilian use. This points up the vital importance of the operation of required blood-testing programs before, during, and after national crises which boost the rate of venereal disease infection.

The procedure used in evaluating the effectiveness of prenatal blood testing was also

used in examining the efficiency of premarital blood testing. Figure 2 shows that, except for a longer time interval, rates are essentially the same as would be expected before the reduction in infant mortality rates became readily apparent.

Prenatal Testing

To investigate the effectiveness of prenatal blood testing in individual States, the trend established by pre-law rates was related to post-law rates in each of the 42 States having prenatal blood-testing legislation. The results were as follows:

1. Fourteen States had an upward trend in infant mortality from syphilis during the 3 years preceding the effective date of the prenatal blood-testing law. After the passage of the law, all of these States had a downward trend in infant mortality from syphilis and experienced significantly lower rates than expected during 5 years following prenatal blood-testing legislation.

2. Two States with a steady level of infant

mortality due to syphilis during the 3 years preceding passage of the prenatal blood-testing law had significantly lower rates than expected during the subsequent 5 years.

3. Twenty-six States had a downward trend of infant mortality due to syphilis during the 3 years preceding prenatal blood-testing legislation. In all of these States the trend in infant mortality due to syphilis continued downward in the years immediately following legislation, in 7 at a faster pace than expected; in 6 at approximately the pace expected; and in 13 at a slower pace than expected.

As an example of the enactment of a prenatal blood-testing law resulting in decreased infant mortality due to syphilis, the observed rates in relation to expected trend are shown in figure 3 for the State of New Mexico. The significant decrease noted during the years 1950-53, following the passage of the law in 1949, is even more remarkable in view of the fact that New Mexico has for some years had the highest rate of infant mortality from all causes in the United States.

It might be asked if the accelerated decrease in infant mortality due to syphilis was confined to States with required prenatal blood-testing legislation or if States without such legislation experienced a comparable reduction in infant mortality rates. Since there is no date of law enactment to use as a point of reference in establishing an expected trend of infant mortality from syphilis in States without prenatal or premarital blood-testing laws, the selection of a year from which to project such a trend becomes fairly subjective. However, the observed trend line for areas without such legislation shows a gradual reduction in infant mortality from syphilis from 1936 to 1950, but how much more of a reduction would have occurred during these years if blood-testing legislation had been in operation is a matter of conjecture.

In addition to the reduction in infant mortality due to syphilis there is evidence to indicate that prenatal blood testing makes a definite contribution to the control of infant mortality from all causes. Presumably this is accomplished by bringing many expectant mothers to prenatal

Figure 2. Composite rate of infant mortality due to syphilis in 40 States before and after enactment of premarital blood-testing law.

Figure 3. Rate of infant mortality due to syphilis in New Mexico before and after enactment of prenatal blood-testing law.

care which they probably would not obtain otherwise.

For the years 1951-53 the total infant mortality rates were significantly lower in the group of States with prenatal blood-testing laws. Since the States without these laws are not those with unreasonably high infant mortality from causes other than syphilis, it seems reasonable to assume that the lower infant mortality in States with prenatal blood-testing laws may have been due at least in part to increased

prenatal care incident to the required blood-testing program.

Race Distribution

Race distribution is, of course, a very real factor in measuring infant mortality. To determine the results of prenatal blood testing, specific for race, we have prepared some comparative material on areas with and without the law with varying percentages of white population. The 7 areas without prenatal

laws (6 States and the District of Columbia) happen to cluster in 3 geographic areas where white births comprise the following percentages of total births: 63 percent in Alabama, Tennessee, and Mississippi; 75 percent in the District of Columbia and Maryland; and 98 percent in Minnesota and Wisconsin. Total infant mortality in neighboring States with a prenatal blood-testing law and of a comparable proportion of white births was compared with the total infant mortality in these three areas. In every case, regardless of race distribution, the infant mortality rate among the white population was lower in 1953 in States with the prenatal blood-testing law than in States without such a law. Conversely, in all instances, the nonwhite infant mortality rate was higher in States with the prenatal blood-testing law than in States without this law, with the differential becoming greater as the number of nonwhites in the population decreased.

There may, of course, be a number of factors contributing to this paradox among nonwhites. One factor is the administration of the law. This was borne out by a study of New York City birth certificates which asked whether a prenatal blood test had been made (see table).

Results of a study on prenatal care in New York City, 1951

| Race | Number of births | Late or no prenatal STS | |
|-------------------|------------------|-------------------------|---------|
| | | Number | Percent |
| White..... | 4, 905 | 639 | 13. 0 |
| Puerto Rican..... | 521 | 228 | 43. 8 |
| Nonwhite..... | 1, 138 | 441 | 38. 8 |

From birth certificate data it was found that in 13 percent of the white births studied, the mother either had no serologic test for syphilis (STS) or had had an STS only during the last trimester of pregnancy, as compared with 44 percent among Puerto Rican and 39 percent among nonwhite pregnant women. If only 60 percent of nonwhite pregnant women are being adequately tested for syphilis in New York City, where a prenatal law has been in effect since 1938 and where medical facilities are known to be available, there is reason to believe

that administration of the prenatal law is even less effective in areas where prenatal care is less adequate. With higher percentages of nonwhites in an area, the administration of the law becomes less effective for this group.

Penicillin Therapy

Another factor which adds to the difficulty of evaluating prenatal blood testing is penicillin therapy. This has undoubtedly affected, even to the point of destroying trend comparability, the two measures we use to estimate the incidence of congenital syphilis, namely, reported number of cases and infant mortality due to syphilis. With penicillin readily available and carrying little therapeutic risk, many physicians have adopted the policy, in cases of doubtful diagnosis, of treating infants on a prophylactic basis. Since these cases are not diagnosed, they are not included in the congenital syphilis case rate. On the other hand, treatment of syphilitic babies with penicillin has been so successful that infant mortality due to syphilis is no longer comparable to this rate during the arsenical-bismuth era. Thus, the reductions in the incidence of congenital syphilis may be due, for the most part, to therapy rather than to the actual prevention of cases. Very recently, with the alarm aroused by increased reactions to penicillin, this therapy is in many cases being withheld, which complicates the trend pictures even more, but at the same time points up the need for prenatal screening.

Congenital Syphilis

Another facet of the evaluation of required blood-testing programs centers on the difficulty of diagnosing congenital syphilis. In infants, there may be no physical signs of the disease, and the serologic test is sometimes negative until 3 or 4 months of age. In present-day venereal disease control programs, many years pass before it is certain that all children at risk have been screened for congenital syphilis. Mass blood-testing programs are designed for those who have reached early adulthood, and we know from experience that very few cases of congenital syphilis are found in blood-testing surveys. Hence, the child with congenital syphilis often remains undiscovered and un-

treated until he enters school, applies for a job, enters military service, or plans to marry. An effective prenatal blood-testing law will protect him from infection before birth. For instance, in the fiscal year 1955, 4.5 percent of the reported cases of congenital syphilis were in infants less than 1 year old at time of discovery of syphilis, 2.2 percent in children aged 1-4 years, 8.1 percent in children aged 5-9, and 85 percent were in children 10 years old or older. In numbers, this means that 4,700 of the 5,515 patients with congenital syphilis reported in fiscal year 1955 were approaching or had reached adulthood before detection of the disease. This number, added to the undiscovered reservoir of cases still in the population, represents, in a measure, the past failures of prenatal blood testing and points up the need for more effective administration of the law.

Premarital Testing

Reactivity rates in premarital blood testing have not declined in the period 1951-54, the only period for which we have data available. This maintained level of reactivity indicates that whatever reasons there may have been for the original enactment of the laws, these reasons may still be valid. The argument may be raised that premarital blood testing has not discovered an appreciable number of cases of early syphilis; however, it must be kept in mind that premarital blood testing was not expected to find much lesion syphilis. Conservative estimates indicate that 12,000 to 13,000 previously untreated syphilitic persons are found annually through premarital blood testing. Because of the age-interval of candidates for premarital blood testing, most of the cases of syphilis detected are early latent. Our current epidemiological indexes indicate that each person diagnosed with early latent syphilis names, on the average, 2 contacts, and that 115 cases of syphilis per 1,000 of these contacts examined are found as a result of contact interviewing.

Required blood testing has general health educational value. The very fact that it is required by law is convincing proof to many of the efficacy of such a procedure. Very few people submit to premarital or prenatal blood

testing without some notion of why they are being tested. Premarital blood testing, which in most States is incorporated as part of a physical examination, offers the physician opportunities to find lesion syphilis, to do effective case finding of other diseases, and, in some cases, to provide sex education and marriage counseling. Premarital and prenatal blood testing in the control of syphilis are analogous to preventive medicine in other diseases. Since preventive medicine is the very essence of public health, blood-testing legislation is desirable.

As an index of prevalence of syphilis, the need for required blood testing continues. Perhaps of greater importance than as a statistical measure of control, required blood testing screens a segment of the population in which the incidence of early syphilis must be kept at a minimum if venereal disease control is to be maintained. Furthermore, the value of prenatal and premarital blood-testing laws must be measured against the number of cases of syphilis prevented by the existence of these laws as well as in terms of the cases found by their operation.

As a possible example of this dual evaluation of blood-testing laws, 100 cases of early syphilis detected among 100,000 persons examined premaritally would result in an infection rate of only 1 case per 1,000 examined. However, in terms of prevention, the 100 additional new infections which could have developed in prospective marital partners, plus the likely congenital infections in offspring of these marital unions, increase this rate to new proportions. By adding to these infections the previous contacts from which the initial 100 infections were acquired, 1 case actually detected among each 1,000 premarital examinees should be increased to perhaps 5 cases (assuming 2 offspring to each union) to measure more accurately the efficiency of premarital epidemiology and case finding.

Summary

Premarital and prenatal blood-testing legislation, when properly administered, contributes to venereal disease control by (a) detecting and bringing or returning to treatment persons with syphilis, (b) preventing the transmission of syphilis to marital partners, (c) protecting un-

born children from congenital infection, (d) reducing morbidity and mortality due to syphilis and to other causes among infants by encouraging prenatal care, and (e) providing opportunities for general health education, sex education, and marriage counseling. Despite the accomplishments of required blood-testing

programs during recent years, there remains much to be done toward the prevention and control of congenital syphilis. As long as cases of congenital syphilitic infection continue to be found in our population, there is a definite need for strict enforcement of blood-testing legislation.

Revised Statement of Rheumatic Fever Prevention

Revised recommendations for preventing first and repeat attacks of rheumatic fever are incorporated in a new edition of the American Heart Association's statement on Prevention of Rheumatic Fever and Bacterial Endocarditis Through Control of Streptococcal Infections.

This is the second revision of the statement, prepared by the AHA Committee on Prevention of Rheumatic Fever and Bacterial Endocarditis to keep pace with the progressively growing body of knowledge and experience in this field. The committee points out that no recommendations can be considered final at this time. Revisions and changes will be made as new knowledge may indicate.

Principal Changes

Following are the principal changes in the recommendations:

1. Greater emphasis is placed on the value of throat cultures in diagnosing streptococcal infections with a view to stimulating an increased use of cultures, particularly when clinical manifestations alone are inconclusive.

2. The recommended duration of prophylaxis has been qualified. The committee reaffirms its view that continuous prophylaxis should be maintained indefinitely for known rheumatic subjects, but it recognizes that some physicians may wish to make exceptions in certain of their adult patients, particularly those without heart disease who have had no rheumatic attacks for many years.

3. Monthly injection of 1,200,000 units of benzathine penicillin G intramuscularly is now listed first among prophylactic methods. The committee also indicates that it is preferable, if oral penicillin is chosen as the method of prophylaxis, to prescribe 200,000-250,000 units twice daily, rather than once.

providing an additional safeguard against breakthroughs which have been reported with the smaller dosage.

Bacterial Endocarditis Prophylaxis

Also revised in the statement are the recommended dosages for prophylaxis against bacterial endocarditis in patients with rheumatic or congenital heart disease who are obliged to undergo such surgical procedures as dental extractions and tonsillectomies. Emphasizing that the dosage regimens used for long-term prophylaxis of streptococcal infections are inadequate for this purpose, the committee recommends that high blood levels of penicillin be maintained for several days (rather than, as previously stated, on the day of operation alone) to prevent organisms from lodging in the heart valves during the period of transient bacteremia.

In general, the combined oral and parenteral route of administration is preferred, as follows: oral penicillin (200,000-250,000 units four times a day) for the 2 days before and the 2 days after surgery; the same dosage of oral penicillin on the day of surgery plus 600,000 units of aqueous penicillin with 600,000 units of procaine penicillin shortly before operation. Alternative recommendations are included for situations in which injection is not feasible or penicillin is contraindicated.

The revised statement appears in the December 1956 issue of *Modern Concepts of Cardiovascular Disease* and in the January 1957 issue of *Circulation*. An outline of a recommended method for culturing beta hemolytic streptococci from the throat is also being made available by the association and may be obtained from local heart associations or the American Heart Association, 44 East 23d Street, New York 10, N. Y.

Serology Control Program Of the Venereal Disease Research Laboratory

By AN HARRIS
and HILMED N. BOSSAK, B.S.

THE SEROLOGY CONTROL program of the Venereal Disease Research Laboratory was evolved to assist State laboratories in attaining and maintaining a high level of efficiency in serologic testing. Through these State laboratories, the testing efficiency of all laboratories of this country performing serologic tests for syphilis may be favorably affected. This program has nine integrated segments, each of which is of little value as a separate entity, but which, collectively, have been effective in reaching the objective with a minimal expenditure of time and money. The serology control program has also served as a pattern of operation used by several States as a service to the laboratories within their jurisdictions. Available to the central laboratories of the 48 States, the District of Columbia, Alaska, Hawaii, Puerto Rico, and the Virgin Islands, the services of the program include:

Providing a laboratory manual prepared by the staff of the Venereal Disease Research Laboratory.

Providing reference-standard serologic reagents prepared by the staff of the Venereal Disease Research Laboratory.

Inspecting laboratory serology control programs.

Conducting scheduled training courses.

Conducting field refresher training courses or workshops.

Standardizing and supplying dehydrated control serum.

Conducting hemispherewide serologic evaluation studies on a continuing basis.

Mr. Harris is director of and Mr. Bossak is a bacteriologist with the Venereal Disease Research Laboratory, Public Health Service, Chamblee, Ga. Their paper was presented at the First International Symposium on Venereal Diseases and the Treponematoses, Washington, D.C., May 28-June 1, 1956.

Participating as a control or co-control in intrastate serologic evaluation studies.

Offering a *Treponema pallidum* immobilization (TPI) testing service, nationwide, through the State and Territorial laboratories.

Manual of Serologic Tests

A Manual of Serologic Tests for Syphilis has been prepared with the assistance of the authors of the tests and is revised at appropriate intervals. The manual contains general information about equipment; cleaning and care of glassware, antigens, and other reagents used in serologic tests; the effect of room temperature on test results; reporting of serologic test results; and laboratory control of test performances. Technique outlines, including recommendations for equipment, glassware, reagents, and step-by-step procedure for APIA reference, Hinton, Kahn, Kline, Kolmer, Mazzini, Rein-Bossak, and VDRL tests, are contained in the 1955 edition (1). Instructions are given in the appendix for the collection and preservation of sheep red cells, preparation and preservation of complement, use of merthiolate as a bacteriostat for spinal fluid, and a recommended method for quantitative determination of spinal fluid protein. This manual has been revised at approximately 5-year intervals in order to stay abreast of acceptable changes in the field of serology. The 1955 edition is the latest revision.

Services to Laboratories

Standardized antigens and other reagents for the tests listed in the Manual of Serologic Tests for Syphilis are prepared and made available for check-testing purposes to commercial or State laboratories that manufacture or purchase these reagents. During past years, the older type, lipoidal antigens were standardized and distributed for use in check-testing but this activity is now confined to the cardiolipin-type antigens. Verification testing of antigens prepared by State laboratories is also done on request. Agreements have been reached under which samples of VDRL antigen are submitted to the Venereal Disease Research Laboratory for check-testing and approval before sale by commercial laboratories in this country.

State laboratories are visited on request for consultation and for reviewing their serology program (testing, laboratory control, training, and laboratory visitation). Written reports of observations, commendations, and recommended changes, if any, are submitted to the State laboratory director and the State health officer. This service will be more fully described in a later paper.

Training Courses

Training courses are regularly scheduled at the Venereal Disease Research Laboratory. Nine 2-week courses were scheduled during the fiscal year 1956; 10 courses were held. Applications from this country for these 2-week courses must be signed by the State health officer or the State laboratory director, unless the applicant is an employee of the Public Health Service, in which case the application must be approved by the medical officer in charge of the laboratory where the applicant is employed. Trainees are accepted from Armed Forces installations in this country and from the World Health Organization, the Pan-American Sanitary Bureau, and employees of central laboratories in other countries. Schedules of courses for each fiscal year are distributed before July 1, and reservations are made as soon as applications are received. Application lists are closed 1 month before the dates the courses are to start.

Five courses titled "Serology of Syphilis" were scheduled for the fiscal year beginning July 1956. These courses provide refresher training to senior operating personnel of State and Public Health Service laboratories. They are composed of lecture, demonstration, and participation periods covering the most widely used American methods for the serodiagnosis of syphilis, with references to latest developments in this field.

The two courses in management and control of syphilis serology by the regional laboratory are designed for assistant laboratory directors and senior laboratory staff members and include review of interlaboratory serologic evaluation studies, laboratory inspection procedures, demonstration of antigen check-testing and standardization, and preparation of control serum.

Courses about tests for syphilis using the *Treponema pallidum* include lectures, demonstration of and class participation in the immobilization (TPI), agglutination (TPA), complement-fixation (TPCF), immune-adherence (TPIA), and other tests which use the virulent *Treponema pallidum* as an antigen source. The complexity of these tests requires that these classes be limited to small groups, so it has been necessary to schedule additional classes when large numbers of qualified applicants have applied. Applicants for these courses should have had adequate experience in the field of serology and be in supervisory positions.

Field refresher training courses are also held in cooperation with State department of health laboratories. On-the-job training is also accomplished during visits to Public Health Service laboratory facilities.

Control Serum

Dehydrated control serum for serologic tests for syphilis is offered to the State laboratories and to Public Health Service laboratories on a continuing basis. Twenty-six ampules of serum, considered to be a 6 months' supply when used at the rate of one ampule per week, are sent with a protocol showing the reactivity of each lot of serum in all of the tests performed at the Venereal Disease Research Laboratory. Continuous use of this control serum will allow the laboratories to determine the relative reactivity of their tests as compared with the same tests performed at the Venereal Disease Research Laboratory and, secondly, will show whether the reactivity of their tests is remaining at a constant level or is varying from day to day. The laboratories that use this serum do not report their findings to the Venereal Disease Research Laboratory, since this is not considered to be an evaluation service.

Serologic Evaluation Studies

The Public Health Service Serologic Evaluation Study is presently being conducted by distributing 20 samples of prepared sterile serum to each of 62 participating laboratories in each of 10 months of the fiscal year. During

the remaining 2 months, all reports are tabulated and an analysis of comparative results is issued. Laboratories participating in this study during the fiscal year 1956 included the central laboratories of the 48 States, the District of Columbia, Alaska, Puerto Rico, Hawaii, Mexico, and Canada, plus the Kahn, Kline, Kolmer, Hinton, Rein, and Mazzini laboratories and the Venereal Disease Research Laboratory. This type of serologic evaluation study produces data that may be used to ascertain relative efficiency of many laboratory performances of each type or kind of test as compared with the test-author results. In order to make available to the participating laboratories some comparative results before the yearly report is analyzed, a report of the results obtained at the Venereal Disease Research Laboratory each month, with all procedures, is sent to all participating laboratories as soon as their monthly report is received.

A similar, but smaller, serologic evaluation study is presently being conducted for the laboratories of Public Health Service facilities. In this study, 10 samples of prepared serum will be sent monthly for 5 months of this fiscal year to each of 26 Public Health Service laboratories. A report of the results obtained with the VDRL slide test and the Kolmer test at the Venereal Disease Research Laboratory is returned to the laboratories participating in this study as soon as their monthly reports are received.

Use of VDRL Services

The central laboratories of all 48 States, the District of Columbia, Alaska, Hawaii, Puerto Rico, and the Virgin Islands have received one or more of the services referred to in this report during the recent past. In the calendar year

1955, these laboratories utilized the services and control functions of the Venereal Disease Research Laboratory 261 times, in addition to submitting 2,575 serums for TPI testing. Additional services were given to the central laboratories of other countries either directly or through the function of the Venereal Disease Research Laboratory as a reference laboratory for the World Health Organization.

TPI Testing Service

The *Treponema pallidum* immobilization (TPI) test has been offered since January 1955 as an additional reference service, on a nationwide basis, through the laboratories of State health departments, by the Venereal Disease Research Laboratory. Criteria for acceptance of specimens for this testing are stipulated. Blood specimens are sent to State laboratories, where sterile serum is separated and forwarded to the Venereal Disease Research Laboratory. Each specimen of serum must be accompanied by a completed clinical data sheet containing statements about evidence or history of treponematosi; syphilis in the family; other venereal diseases; record of known STS; diseases other than treponematosi especially those presumed to elicit nonspecific reactions in STS; and the opinion of the attending physician regarding present diagnosis. Reports of TPI tests are sent to the respective State laboratories for forwarding to the submitting physician. During the first months of 1956, requests for this service were received at the rate of approximately 100 per week.

Occupational Health on Farms

By HENRY N. DOYLE

HEALTH AGENCIES have many as yet undischarged responsibilities toward rural Americans. To comprehend the responsibilities of official agencies for occupational health on farms, it is useful to grasp the extent of industrialization of American agriculture.

The population of the United States in 1910 was 92 million. Today, it is 166 million, an increase of 80 percent. In 1910 there were 322 million acres of cropland. Today there are 350 million acres of cropland, an increase of only 9 percent. Yet, this acreage produces more than enough food for our expanded population. It is estimated that 310 million acres will supply our 1960 population, thanks to the increase in productivity per acre. Improved soil management, such as erosion control and the use of fertilizers and other agricultural chemicals, including pesticides and weedkillers, have contributed part of this gain. Power machinery has increased the farmer's capacity to plow, sow, harvest, and manage livestock. Furthermore, market crops now grow on about 75 million acres formerly used to grow feed for the horses and mules which have been replaced by power machines.

Mechanization has made it possible for farms to produce more than enough for our present needs through the efforts of only 6,500,000 farm workers, or 11 percent of our working popu-

lation, whereas in 1910, 11,600,000, or 31 percent, were employed in agriculture.

The number of American farms in 1954 was 5,425,000, as compared with about 6,600,000 in 1910. More important, half of our present farms produce nine-tenths of the crops. This concentration offers a striking parallel to many industries in which a small number of large companies account for a high percentage of the total production.

Even as large manufacturing concerns tend, with large-scale operations, to employ the latest advances in mechanization, so, and frequently to a greater degree, large farms tend to employ mechanical equipment. The capital investment associated with many of the new mechanical farm devices often runs to a sum which is not economical for a single-family farm.

Some idea of how mechanization has progressed in farming may be obtained from United States Department of Agriculture statistics which reveal that between 1941 and 1952 the number of tractors increased from 1.7 million to 4.4 million (159 percent), the number of grain combines from 225,000 to 940,000 (318 percent), and the number of mechanical corn-pickers from 120,000 to 635,000 (429 percent). The increase of total power on American farms during that period exceeded 70 percent. Farm output per man now has approximately doubled in the 15 years since Pearl Harbor.

Agricultural changes during the past generation, therefore, have come to create new working conditions even as industrialization changed working conditions in mines and mills.

How do these new conditions affect the health and safety of farm workers? Farming is intrinsically hazardous. Injuries have always been frequent on farms. Although statistical

Mr. Doyle is assistant chief of the Occupational Health Program, Public Health Service. His paper and the summaries of the papers on silicosis and X-ray exposure (p. 149) are based on talks delivered to the American Conference of Governmental Industrial Hygienists, Philadelphia, April 21-24, 1956.

evidence is lacking, experience has led us to expect many injuries from the handling of farm horses. A limited survey in one county within the past 6 months showed that 8 out of 29 recent accidents were associated with horses. Even with mechanization, farmers tend to keep a few horses. Of 44 farms visited in this survey, 36 had at least one horse. The total was 182.

Other farm animals also, particularly bulls, present hazards to farm hands. Injuries from the use of sharp or heavy tools or the stress of heavy lifting also are common farm afflictions, frequently resulting in chronic conditions, herniation, paraplegia, or impairment of vision.

The danger of infections from injuries incurred on the farm must be considered much greater than that in industry. This danger is heightened by the nature of the working environment, the inaccessibility of first-aid facilities, and the absence of interest in giving prompt care to minor wounds and other dermatological conditions. The prevalence of the tetanus hazard on farms is well recognized by physicians, but other organisms also must be considered.

A number of bacterial diseases are associated with agricultural work. Brucellosis, or undulant fever, is thought to be the most common one, but reliable statistics are lacking. It is not likely that all brucellosis is correctly diagnosed or that all diagnosed cases are reported. One factor contributing to the incidence of brucellosis is that rather than call upon a veterinarian, many farmers themselves vaccinate cattle and thereby risk accidental infection. Other diseases of significance on farms include anthrax, erysipeloid, leptospirosis, tularemia, bovine tuberculosis, and various forms of salmonellosis.

By occupation, the farmer is exposed also to viral and rickettsial diseases, including equine encephalomyelitis, psittacosis, Q fever, and Rocky Mountain spotted fever. There is a long list of mycotic diseases, of which *actinomycosis* and *histoplasmosis* are examples. A number of parasitic diseases also are potential farm hazards.

Moving from these biological hazards to physical agents, we find that farm work involves exposure to extremes of temperature,

both high and low. Heat exhaustion and heat stroke undoubtedly affect many farm workers. Another condition of possible significance is skin cancer, produced by prolonged exposure to the sun's rays.

The increased use of machines has brought a whole group of hazards new to agriculture. Noise exposures, for example, may now be sufficient to affect the hearing of farmhands who operate machines for extended periods. When more is learned about the problem of vibration, it may also be found to have adverse health effects on agricultural workers. Maintenance and repair work on farm machinery introduce hazards associated with welding.

Accidents incurred in the use of farm machinery represent one of the major categories of farm hazards. Accident rates in agriculture are far above industry as a whole. In 1951 only the mining and construction industries had higher death rates: Agriculture had 60 fatal work accidents per 100,000 (a total of 3,800) as compared with a rate of 25 per 100,000 for all industries. The injury rate, according to the National Safety Council, was 4,930 per 100,000 as compared with 3,240 per 100,000 for all industries.

Hazard From Chemicals

In addition to biological and physical hazards, the industrial hygienist who looks at present-day farming is struck forcibly by the number of toxic chemicals in use. Although many of these are soil conditioners and fertilizers involving little hazard, the majority are insecticides, fungicides, rodenticides, nematocides, and weedkillers which are employed specifically because of their toxic properties. While some are comparatively safe, nearly all present some degree of danger, and some must be classified as extremely hazardous. In particular, the heavy metals, such as lead, arsenic, and mercury, the halogenated hydrocarbons, and the organic phosphates present serious potential dangers to the people using them and sometimes to others working or living in the vicinity.

In dealing with industrial exposure to hazardous materials, we frequently express the view that any material, regardless of toxicity, can be used safely provided that proper

control measures are employed. The same philosophy might be applied to agriculture, but assurance of proper control measures is harder to obtain, at least at the present time. The reasons are apparent. Industrial operations are usually performed in a fixed location where exhaust ventilation or other suitable control methods are feasible. Industry has been subjected to fairly extensive and intensive educational programs on health and safety for at least a generation. Large companies usually have full-time safety and medical departments alert to potential dangers. Furthermore, personnel of insurance carriers and official agencies make frequent visits to industrial plants to check for possible hazards.

On the other hand, agricultural workers generally have little idea of the hazards of handling and applying powerful chemicals. Although most chemicals of this type carry warnings on the container labels, the tendency is to pay little or no attention to the labels, particularly if a material has been used previously without untoward incident.

Moreover, the methods of application are almost as varied as the materials used. Many of these methods present dangers that would not be tolerated in manufacturing establishments. For example, the application of fumigants such as carbon tetrachloride in connection with grain storage may employ techniques that would horrify an industrial hygienist. A recent farm survey observed workers tying handkerchiefs over their faces to protect themselves from heavy concentrations of carbon tetrachloride.

The hazards of farm life are not to be ignored. And they are not ignored although much remains to be done to protect the farmer's health.

Health Services for Farm Workers

Occupational health programs are conducted in official agencies either because of laws specifically concerning industrial working conditions or because of broad powers regarding the protection of health. Virtually all such programs were introduced to cope primarily with problems associated with manufacturing, and, sometimes, also mining. Few

of them gave much thought initially to the farm worker. In recent years, certain State officials have devoted attention to specific farm problems brought to their attention. For example, in Florida, in 1952 there were 46 claims for parathion poisoning filed; in 1953, there were 45. The Florida State division of industrial hygiene has since conducted an educational campaign among citrus grove and truck garden owners on the hazards of insecticides and preventive measures.

Also, California has conducted investigations of the high incidence of occupational disease among its agricultural workers. In 1954, of 23,101 reports of occupational disease in California, 3,143 (13.6 percent) were for agricultural workers.

In addition to purely occupational influences, the health of many farm workers is affected by environmental factors that are much less significant among present-day urban workers. Farm laborers, especially migrant workers, sometimes must live where housing and sanitation levels are far below those now considered as acceptable or safe. Large numbers of workers move from one State to another in pursuit of peak season farm work, and they stop at places where waste disposal is primitive, where water supplies are of questionable quality, where food spoilage is difficult to prevent, and where protection against flies and other disease carriers is absent. With this mobile population, numbering more than the citizens of several States, public health considerations demand far more than control of the traditional occupational diseases. In addition to basic sanitation, there must be answers to knotty questions of medical care for individuals not eligible for service available to permanent residents. Otherwise, it is reasonable to expect that transient workers will be permitted to carry communicable disease to every community that summons their services.

While rural health services can use all available community resources, occupational health personnel must not overlook their special responsibility. Industrial hygienists, in checking the working environment in factories and mines, are also concerned with the water supply, washing facilities, waste disposal, and food sanitation. Nor should they neglect these

points with respect to farm work, or, for that matter, in other situations where rural workers are housed temporarily, as in construction camps. Since such responsibilities also rest upon other personnel in State and local health agencies, policies for the best utilization of available man-hours must be developed to meet the individual situation. It is important, however, to recognize the place of environmental and medical care services in the occupational conditions of agricultural workers.

South Dakota and Iowa Programs

As stated before, a number of State occupational health officials have concerned themselves, to a limited extent, with specific or selected health needs of agricultural workers. To the best of our knowledge, however, no agency has ever considered the total need, with the objective of ascertaining the extent and severity of health problems on the farms of its State. This approach, which has been applied effectively by the States in planning logical and sustained programs for the improvement of worker health in industry, must now be used in agriculture if we are successfully to protect and improve the health of the farm family and its helpers.

The first stirring of activity in this direction came in 1955, when the South Dakota Department of Public Health requested assistance in planning an occupational health program for the State. In response to this request, the Public Health Service suggested that the program be developed to give industry and agriculture equal consideration from the start. To help develop such a program, the Occupational Health Program of the Public Health Service assigned a veterinarian to South Dakota in September 1955. Through this project it is hoped to evaluate the effectiveness of certain

survey techniques and to develop useful information regarding occupational health problems and methods for their attack.

Coincidentally, during 1955 the State University of Iowa Medical School established an Institute of Agricultural Health which will study similar questions in Iowa.

It is significant, we believe, that these related projects were independently conceived and started at this time. Although the existence of health and safety hazards on the farm has been recognized by public health authorities for some years, the South Dakota and Iowa programs represent the first positive steps taken toward a comprehensive approach to the problem.

While some findings from these two States may become available relatively soon, other States need not wait for them before taking stock of the adequacy of their activities with respect to this particular segment of the employed population. Indeed, because of variations in crops, climate, soil, and other factors, problems will be found to differ in each locality, and all States can contribute appreciably to scientific knowledge while carrying out a public health activity of real merit.

The subjects which need exploration are numerous. Study needs to be made of the toxicology and proper application of chemicals, of the safe use of mechanized equipment, of the general health status of agricultural workers as compared with the rest of the population, of the effectiveness of educational measures, and of the availability of health resources.

This is a new and complex field confronting the industrial hygienist. Occupational health needs on the farm may not be readily anticipated, but in every State where agriculture is a significant industry, an earnest beginning should be made to meet this public health responsibility.

Pediatricians Receive Low X-ray Doses

X-rays as an occupational hazard of physicians have been associated with a relatively high incidence of leukemia in the medical profession.

In an effort to measure the probable routine exposure to radiation of certain specialists in private practice (in contrast to the number of such studies that have been pursued in hospitals), representatives of the Public Health Service arranged to survey the offices of 55 pediatricians in Hamilton County, Ohio.

All but 10 of the physicians used X-ray equipment, mainly for fluoroscopy. The survey was confined to this use. Instruments measured the time the fluoroscopes were in operation for 2 weeks; pocket chambers and film badges determined the exposure of the physicians in the period studied; the team inspected the condition and operation of the equipment; and the medical officer examined the physicians for evidence of gross radiation injury.

The condition of the equipment presented shock hazards, apart from the danger of radiations. Nearly half of the machines were not grounded. Several, thought to be grounded, were not. Also, certain high voltage conductors were exposed.

Scatter or stray radiation at points where the fluoroscopist would be exposed exceeded 50 milliroentgens per minute in 14 instances. Patient's exposure to 6 of the machines exceeded 20 roentgens per minute. Another 16 were above 10 roentgens per minute. The recommended limit is 10 roentgens per minute. For infants and children, it should be much less than that.

The physicians with highest exposures were able to identify and correct errors in procedure.

By Peter J. Valac, B.S., electronics scientist, and Mitchell R. Zvon, M.D., formerly surgeon, Occupational Health Field Headquarters, Public Health Service, Cincinnati. Dr. Zvon is now with Kettering Laboratory, Cincinnati. The full paper is to be published in the American Industrial Hygiene Association Quarterly for March 1957.

Three had worn no lead garments. One used a beam of high intensity. Another held the patient, a child, and received high dosage to his arms.

The saving factor in the situation was that more than half of the fluoroscopes were used less than 1½ minutes a week. Consequently, most exposures of physicians were well below present recommended limits.

Silicosis Prevalence Persists in Industry

Silicosis persists in the United States both as an occupational hazard and as a cause of chronic if not disabling illness among many who were exposed before industrial safeguards had been established. This finding is based on a study of official records from scattered sources, described in some detail at the conference and in other publications.

The study, undertaken by the Division of Special Health Services, Bureau of State Services, Public Health Service, aimed to develop answers to four questions:

1. What is the prevalence of silicosis in the United States?
2. What are the characteristics of the silicotic population?
3. Are a significant number of new cases developing among workers entering dusty trades for the first time in the past 20 years?
4. What aspects of dust exposure need further study?

The findings of the study are to be presented in a special bulletin.

Preliminary observations indicate that the prevalence of silicosis may be several times the number of cases, more than 10,000 that were compensated or reported in one form or another in 22 States in 1950 to 1954, inclusive.

By Victoria M. Trasko, program adviser, Occupational Health Field Headquarters, Public Health Service, Cincinnati.

Geographic variations in prevalence were affected not only by industrial patterns but also by legal variations. In States where partial disability is compensable, it was to be expected that a relatively greater number of cases would be reported.

A strong indication that the number reported is below the real prevalence figure is found in the fact that in the 5-year period probably 10,000 died from occupational lung disease, but of the more than 10,000 cases reported for this study only 4 of 5 persons are known to have died.

The silicotic patients studied were in the main elderly. Of 4,814 analyzed in all stages of the disease, only 120 were under 35, 1,025 were age 35 to 49, 2,437 were 50 to 64, and 1,232 over 65. In effect, three-fourths were more than 50 years old. But in certain States, depending on the source of information, a much higher proportion of the men were relatively young. This was true especially in eastern States.

These findings provide a partial answer to the third question. Although many cases are the consequence of exposure in days when protective measures were lacking, there are enough young men who must have been exposed in recent years.

The mobility of the working force, with frequent job changes, hinders efforts of the epidem-

ologist to determine which industries are most productive of silicosis, but the highest proportion of cases appear to have been associated with mining, especially coal mining and secondarily metal mining. Of the forms of manufacture associated with silicosis, foundries appear to have been as productive of silicosis as metal mining. This analysis only suggests the most productive sources of the disease, not the relative dangers in the industries concerned.

To judge by the numbers of young men affected, no industry can be certain that it is protecting completely its employees from exposure to dust. Sufficient evidence was uncovered to suggest that either the application of dust control measures is not universal or other factors are involved. The studies suggest that, with relatively light and brief exposures to dust, the disease may take longer to develop than in the past, a possibility that cannot be determined for some years to come.

Such questions warrant further study, especially in view of the rising trend of applications for compensation or public assistance for silicotics. Future studies will be facilitated if diagnosis and reporting improve, if diagnoses and terminology are consistent, and if standards are applied to criteria of disability and to supervised employment of nondisabled silicotics.

Venereal Disease Course

The 26th Venereal Disease Postgraduate Conference for Physicians, sponsored by the University of Tennessee College of Medicine and the Public Health Service, will be held at the College of Medicine in Memphis, April 18-20, 1957.

The course is designed to acquaint the practitioner with the latest developments in diagnosis, treatment, and management of the venereal diseases. Discussion leaders for the course will be drawn from university faculties, Public Health Service personnel, and other outstanding authorities in the field.

No tuition will be charged. Applications for admission are to be sent to Dr. Henry Packer, Department of Preventive Medicine, University of Tennessee College of Medicine, Memphis 3, Tenn.

Analyzing the Tuberculosis Case Register

By HERMAN E. WIRTH, M.D., M.P.A., and BEN Z. LOCKE, M.S.

THE FIRST statewide analysis of local tuberculosis case registers in New York State, excluding New York City, was undertaken in 1952. This analysis was based on certain data contained in the registers maintained by 38 city, county, and State health district jurisdictions. The objectives were to determine the number of cases requiring supervision; to study the characteristics of known cases with respect to age, sex, residence, stage of disease, clinical status, sputum status, and type of supervision; and to evaluate the effectiveness of control activities.

The methods used and results obtained were distributed to all full-time health officers concerned and were published in detail (1). Subsequently, regional conferences were held for three major areas, Buffalo, Rochester, and Albany, for the purpose of reviewing the reported findings and of exploring methods for solving the questions raised by the analysis. These regional conferences, consisting mainly of informal roundtable discussions, were attended by regional and local health administrators, tuberculosis hospital directors, supervising public health nurses, program directors, and staff statisticians as well as representatives of local voluntary tuberculosis associations.

In 1955 a second statewide analysis was conducted from February through June to obtain similar data and to determine what changes

had occurred. The second analysis was also desirable to ascertain the indirect effects of the widespread use of antimicrobial drugs, the emergence of treatment plans on a nonhospitalized basis, and the emphasis on resectional surgery. In addition, there was the need to know what administrative steps had been taken locally to provide more and better service, streamline procedures, remove "deadwood" from the registers, and encourage possible savings. Thus, a fourth objective in the 1955 analysis was a review of the epidemiological and administrative changes in the interim period. Certain items of the 1952 analysis were discarded and other more significant ones included. At the time of the second analysis, 40 local agencies were maintaining case registers.

Administrative Aspects

The value of the case register to administrators depends on the up-to-dateness of entries relating to the persons registered. For the health officer, the register must present the significant facets of the tuberculosis problem in the community if he is to initiate in proper degree those activities needed to resolve the problem. Such activities as case and contact finding, nursing supervision, laboratory and X-ray examination, clinical consultation, treatment, hospitalization, and disposition can only be effectively conducted with the aid of timely data periodically obtained and promptly recorded in adequate detail. This need has been stressed often (2-5).

Of 23,112 cases contained in registers, 4,807 were excluded from the 1955 study because their retention in the visible case registers was not

Dr. Wirth, who has been with the New York State Department of Health since 1948, is associate director of the division of tuberculosis control. Mr. Locke, now chief of the Consultation Unit, Current Reports Section of the National Institute of Mental Health, Public Health Service, was with the New York State Department of Health from 1947 to 1956.

Geographic variations in prevalence were affected not only by industrial patterns but also by legal variations. In States where partial disability is compensable, it was to be expected that a relatively greater number of cases would be reported.

A strong indication that the number reported is below the real prevalence figure is found in the fact that in the 5-year period probably 10,000 died from occupational lung disease, but of the more than 10,000 cases reported for this study only 4 of 5 persons are known to have died.

The silicotic patients studied were in the main elderly. Of 4,814 analyzed in all stages of the disease, only 120 were under 35, 1,025 were age 35 to 49, 2,437 were 50 to 64, and 1,232 over 65. In effect, three-fourths were more than 50 years old. But in certain States, depending on the source of information, a much higher proportion of the men were relatively young. This was true especially in eastern States.

These findings provide a partial answer to the third question. Although many cases are the consequence of exposure in days when protective measures were lacking, there are enough young men who must have been exposed in recent years.

The mobility of the working force, with frequent job changes, hinders efforts of the epidem-

ologist to determine which industries are most productive of silicosis, but the highest proportion of cases appear to have been associated with mining, especially coal mining and secondarily metal mining. Of the forms of manufacture associated with silicosis, foundries appear to have been as productive of silicosis as metal mining. This analysis only suggests the most productive sources of the disease, not the relative dangers in the industries concerned.

To judge by the numbers of young men affected, no industry can be certain that it is protecting completely its employees from exposure to dust. Sufficient evidence was uncovered to suggest that either the application of dust control measures is not universal or other factors are involved. The studies suggest that, with relatively light and brief exposures to dust, the disease may take longer to develop than in the past, a possibility that cannot be determined for some years to come.

Such questions warrant further study, especially in view of the rising trend of applications for compensation or public assistance for silicotics. Future studies will be facilitated if diagnosis and reporting improve, if diagnoses and terminology are consistent, and if standards are applied to criteria of disability and to supervised employment of nondisabled silicotics.

Venereal Disease Course

The 26th Venereal Disease Postgraduate Conference for Physicians, sponsored by the University of Tennessee College of Medicine and the Public Health Service, will be held at the College of Medicine in Memphis, April 18-20, 1957.

The course is designed to acquaint the practitioner with the latest developments in diagnosis, treatment, and management of the venereal diseases. Discussion leaders for the course will be drawn from university faculties, Public Health Service personnel, and other outstanding authorities in the field.

No tuition will be charged. Applications for admission are to be sent to Dr. Henry Packer, Department of Preventive Medicine, University of Tennessee College of Medicine, Memphis 3, Tenn.

Analyzing the Tuberculosis Case Register

By HERMAN E. WIRTH, M.D., M.P.A., and BEN Z. LOCKE, M.S.

THE FIRST statewide analysis of local tuberculosis case registers in New York State, excluding New York City, was undertaken in 1952. This analysis was based on certain data contained in the registers maintained by 38 city, county, and State health district jurisdictions. The objectives were to determine the number of cases requiring supervision; to study the characteristics of known cases with respect to age, sex, residence, stage of disease, clinical status, sputum status, and type of supervision; and to evaluate the effectiveness of control activities.

The methods used and results obtained were distributed to all full-time health officers concerned and were published in detail (1). Subsequently, regional conferences were held for three major areas, Buffalo, Rochester, and Albany, for the purpose of reviewing the reported findings and of exploring methods for solving the questions raised by the analysis. These regional conferences, consisting mainly of informal roundtable discussions, were attended by regional and local health administrators, tuberculosis hospital directors, supervising public health nurses, program directors, and staff statisticians as well as representatives of local voluntary tuberculosis associations.

In 1955 a second statewide analysis was conducted from February through June to obtain similar data and to determine what changes

had occurred. The second analysis was also desirable to ascertain the indirect effects of the widespread use of antimicrobial drugs, the emergence of treatment plans on a nonhospitalized basis, and the emphasis on resectional surgery. In addition, there was the need to know what administrative steps had been taken locally to provide more and better service, streamline procedures, remove "deadwood" from the registers, and encourage possible savings. Thus, a fourth objective in the 1955 analysis was a review of the epidemiological and administrative changes in the interim period. Certain items of the 1952 analysis were discarded and other more significant ones included. At the time of the second analysis, 40 local agencies were maintaining case registers.

Administrative Aspects

The value of the case register to administrators depends on the up-to-dateness of entries relating to the persons registered. For the health officer, the register must present the significant facets of the tuberculosis problem in the community if he is to initiate in proper degree those activities needed to resolve the problem. Such activities as case and contact finding, nursing supervision, laboratory and X-ray examination, clinical consultation, treatment, hospitalization, and disposition can only be effectively conducted with the aid of timely data periodically obtained and promptly recorded in adequate detail. This need has been stressed often (2-5).

Of 23,112 cases contained in registers, 4,807 were excluded from the 1955 study because their retention in the visible case registers was not

Dr. Wirth, who has been with the New York State Department of Health since 1948, is associate director of the division of tuberculosis control. Mr. Locke, now chief of the Consultation Unit, Current Reports Section of the National Institute of Mental Health, Public Health Service, was with the New York State Department of Health from 1947 to 1956.

Table 1. Tuberculosis cases excluded from 1952 and 1955 analyses, New York State exclusive of New York City

| Status | 1952 | 1955 |
|--|-------|-------|
| Total..... | 4,959 | 4,807 |
| Inactive, 18 months or more..... | 3,003 | 2,927 |
| Minimal, arrested 2 years or more..... | 1,141 | 737 |
| Healed primary..... | 291 | 478 |
| Healed nonpulmonary..... | 21 | 137 |
| Suspect..... | 102 | 328 |
| Dead..... | 101 | 200 |

in accordance with the suggested criteria of the New York State Health Department (6-8). Nearly 5,000 such cases had also been excluded from the 1952 analysis (table 1). Thus, there was no significant change despite the fact that removal of the cases would have aided materially in the management of the registers.

Although the health department's criteria for removing cases from the visible registers are not mandatory, their use provides a systematic and standardized approach to related clinical and clerical management problems.

The visible case register, or active file, contains the tuberculosis case and contact register cards on all cases classified as active, arrested, and inactive for less than 18 months among residents of an area administered by a full-time local health officer. The clinical status considered here refers to the 1950 classification of pulmonary tuberculosis of the National Tuberculosis Association.

After excluding these 4,807 cases, 18,305 known tuberculosis patients were recorded as requiring active medical and nursing supervision compared with 19,923 patients in 1952. Thus, the rate per 1,000 population of 2.4 in 1955 as compared with the 2.8 in 1952 represents a decrease of only 14 percent. The rate per 1,000 population in 1955 ranged from a low of 0.8 in Allegany County to a high of 6.2 in Franklin County. In 1952 the rate varied from 0.9 for Schuyler County to 9.9 for Franklin.

In contrast, between 1951 and 1954, the years that best compare with the years in which the data on the case registers were collected, the death rate fell 53 percent and the newly reported case rate fell 26 percent. It is thus apparent that, as the emphasis on new cases is

shifted to all known cases requiring active care, the need for medical facilities, care, and supervision still definitely exists.

Prevalence

The prevalence of known tuberculosis throughout New York State, except New York City, is determined from the visible registers (active files) of the local health offices. Actually, many persons with known disease do not constitute public health hazards and consequently should be withdrawn from the active registers although they may be under the care of a clinic or private physician. Conversely, there are as yet thousands of undetected cases subject to case-finding activities.

Nevertheless, the visible registers in the local health offices provide a count of the tuberculosis cases classified as known cases significant for public health supervision.

No consequential change occurred in the percentage distribution of the various types of tuberculosis in the 3 years that had elapsed since the first analysis (table 2). Each category showed a small decrease in number, the aggregate being 1,618. As previously noted, the known prevalence rate per 1,000 population decreased from 2.8 to 2.4.

There were some minor changes in the percentage distribution by stage of disease of pulmonary cases (table 3).

When the 1952 analysis was presented it was stated, "it is apparent that, with approximately 13,000 known pulmonary cases in the moderately and far advanced stages, tuberculosis in upstate New York requires continued efforts

Table 2. Number and percent of tuberculosis cases in visible registers by type, 1952 and 1955, New York State exclusive of New York City

| Tuberculosis type | 1952 | | 1955 | |
|------------------------|--------|---------|--------|---------|
| | Number | Percent | Number | Percent |
| All types..... | 19,923 | 100.0 | 18,305 | 100.0 |
| Pulmonary..... | 18,118 | 90.9 | 16,692 | 91.2 |
| Other respiratory..... | 938 | 4.7 | 843 | 4.6 |
| Other forms..... | 867 | 4.4 | 770 | 4.2 |

Table 3. Comparison of 1952 and 1955 percentage distributions of pulmonary tuberculosis cases, by stage of disease, New York State exclusive of New York City

| Stage of disease | 1952 | | 1955 | |
|-----------------------|---------|---------|---------|---------|
| | Number | Percent | Number | Percent |
| All stages----- | 18, 118 | 100. 0 | 16, 692 | 100. 0 |
| Minimal----- | 4, 715 | 26. 0 | 4, 068 | 24. 4 |
| Moderately advanced-- | 7, 623 | 42. 1 | 7, 190 | 43. 1 |
| Far advanced----- | 5, 059 | 27. 9 | 5, 053 | 30. 3 |
| Not stated----- | 721 | 4. 0 | 381 | 2. 3 |

by all concerned with public health" (1). The only change needed to make this statement applicable to the 1955 analysis is to note that the number of cases is now only 500 less.

The 1955 analysis reemphasized that the tuberculosis problem is greatest among men, particularly those in the older age group. Males constituted 58 percent of the registered pulmonary cases in 1952 (9) and 62 percent in 1955. The number of males registered as tuberculous remained nearly the same. The rate per 1,000 population was 2.9 for males as compared with 1.8 for females.

The 1955 prevalence rate for women reached a peak at 30 years of age, at which point it was

Figure 1. Rates for newly reported pulmonary tuberculosis cases, 1954, New York State exclusive of New York City.

only slightly higher than the rate for men. The male rate rose to a peak at 60 years. These findings are similar to those of 1952 (9). The configuration of the 1955 prevalence rates was also similar to that of the newly reported pulmonary tuberculosis case rates for 1954 (fig. 1). Of 16,692 persons with pulmonary tuberculosis, only 126 were under 15 years of age.

The 1955 review of the registers also showed that far advanced cases accounted for 34 percent of the pulmonary tuberculosis among males as compared with 25 percent for females.

The men with tuberculosis are about 10 years older than the women, and persons with minimal extent are younger than those with advanced disease (table 4).

These findings substantiate data from other sources and point up the need for continued

Table 4. Median age of pulmonary tuberculosis cases, by sex and stage of disease, 1952 and 1955, New York State exclusive of New York City

| Stage of disease | Median age in years | | | |
|-----------------------|---------------------|-------|--------|-------|
| | Male | | Female | |
| | 1952 | 1955 | 1952 | 1955 |
| All stages----- | 48. 4 | 50. 0 | 38. 2 | 39. 0 |
| Minimal----- | 45. 8 | 45. 7 | 36. 1 | 35. 6 |
| Moderately advanced-- | 49. 0 | 50. 4 | 39. 0 | 40. 1 |
| Far advanced----- | 49. 9 | 51. 4 | 38. 8 | 40. 2 |

and increased case-finding activities among men aged 45 or over.

Sputum Status

Of the 16,692 pulmonary cases on the local tuberculosis case registers in 1955, 3,166, or 19 percent, had a positive sputum in the previous 12-month period. During this same period, however, no sputum information was reported for 8,245 cases, or 50 percent (fig. 2). The percentage of cases with no sputum examinations was only slightly less than in 1952. Sputum examinations represent one of the most important items in case and contact supervision. Since facilities are available, greater

Figure 2. Sputum status of pulmonary tuberculosis cases, 1955, New York State exclusive of New York City.

effort to obtain sputum examinations and record the results are indicated.

Of 7,173 active or sputum positive pulmonary tuberculosis cases, less than half were hospitalized in 1955 (table 5). This is similar to the situation in 1952. Only slightly more than half of the 3,166 cases with positive sputum in the previous 12 months were hospitalized, practically no change since 1952. Is it not foolhardy to be complacent about tuberculosis while 3,740 patients who are either active or sputum positive, or both, remain unhospitalized where hos-

pital facilities are available? Of the 1,475 nonhospitalized sputum positive cases, 325 have never been hospitalized for tuberculosis. Nearly 300 of those hospitalized were treated for less than 6 months in hospitals.

As was pointed out in the 1952 analysis, "For many reasons, some more valid than others, it is difficult to hospitalize and keep hospitalized every case requiring hospitalization. Nevertheless, these reasons should be known and recorded and the number of cases in this category reduced for the welfare of the individual as well as that of the community" (10). It must be constantly remembered that these patients, even if under supervision, constitute a potential health hazard.

Nearly 1,000 active cases have no known medical supervision (fig. 3). Such cases certainly constitute a challenge in the control of tuberculosis. Systematic conference-type review of these cases by the local health officer, the clinician, and the supervising public health nurse could very well result in a significant reduction in the number of unsupervised cases.

Clinical Status

The clinical status, or activity at time of last report, of the 16,692 pulmonary cases in the active files is shown in figure 4. There were changes between 1952 and 1955, namely, a decrease in the percentage of "active" and "activity not stated" categories. Nevertheless, the clinical status of more than 3,000 cases was not stated or was undetermined.

Table 5. Sputum positive ¹ and other active pulmonary cases, by hospitalization status, 1955, New York State exclusive of New York City

| Sputum and clinical status | Number | | | Percent in hospital |
|---|--------|--------------------------|-----------------|---------------------|
| | Total | In hospital ² | Not in hospital | |
| All cases----- | 7, 173 | 3, 433 | 3, 740 | 47. 9 |
| Sputum positive in past 12 months----- | 3, 166 | 1, 691 | 1, 475 | 53. 4 |
| Active----- | 2, 413 | 1, 548 | 865 | 64. 2 |
| Arrested----- | 341 | 24 | 317 | 7. 0 |
| Inactive----- | 117 | 6 | 111 | 5. 1 |
| Not stated or undetermined----- | 295 | 113 | 182 | 38. 3 |
| Sputum negative or no expectoration, active status----- | 1, 024 | 369 | 655 | 36. 0 |
| Sputum not examined or no information, active status----- | 2, 983 | 1, 373 | 1, 610 | 46. 0 |

¹ Cases classified as arrested or inactive may have positive sputum.

² Bacteriological status at time of admission.

Knowledge of the clinical status of cases is not merely of academic interest but has definite administrative value. Clinical status, in addition to the stage of disease, laboratory findings, family conditions, and so forth, determines the amount of supervision the patient and his contacts require. During 1955, 107,406 public health nursing and bedside visits were made to tuberculosis patients and contacts, representing 14.6 percent of the total visits (11). With nursing time at a premium, an up-to-date register will enable the health officer to use nursing service more effectively and economically.

Hospitalization Status

With regard to the pulmonary cases classified by clinical and hospitalization status, the findings are not too dissimilar to those of 1952 (table 6). About one-quarter were hospitalized; of the active pulmonary cases slightly

Figure 3. Sputum positive and other active pulmonary tuberculosis cases not in hospital, 1955, New York State exclusive of New York City.

Figure 4. Clinical status of pulmonary tuberculosis cases, 1955, New York State exclusive of New York City.

more than one-half were hospitalized. Of the nonhospitalized cases 25 percent were classified as active, 33 percent as arrested, 22 percent as inactive, and 20 percent not stated. Between 1952 and 1955 there was a decrease in the percentage of "active" and "activity not stated" groups. Nevertheless, the clinical status of nearly 2,500 nonhospitalized pulmonary cases was undetermined or not stated. Of these patients more than half were under chest clinic supervision and another 10 percent under the care of private physicians (fig. 5). It is recognized that there are delays in determining a patient's clinical status, but prolonged delays affect administrative decisions concerning contact examinations and nursing supervision. When such data are available and yet not entered on the visible register, the value of the register is vitiated.

Nearly 3,000 of the 12,585 nonhospitalized pulmonary cases were under no known medical supervision. About one-third of the 3,130 nonhospitalized pulmonary cases with active tuberculosis were under no known medical supervision (fig. 5). Since, by definition, a person on the register is in need of medical supervision, such unsupervised persons jeopardize their cure and rehabilitation and are potential spreaders of the disease.

Of 13,911 nonhospitalized cases of tubercu-

losis (all forms) 2,451 had not been clinically observed since 1952 (table 7). From such a large number of nonhospitalized cases, many of them active, and the large group of unsupervised cases, there arises the stark realization that much more remains to be done before

Figure 5. Clinical status and type of supervision of pulmonary tuberculosis cases not in hospital, 1955, New York State exclusive of New York City.

tuberculosis may be considered as completely controlled, much less eradicated.

Many of the patients not heard from for 12 months or more, and possibly even some with more recent cases, have undoubtedly moved away, died (without mention of tuberculosis on the death certificate), become lost, or have had inactive tuberculosis for the time period specified for transference from the administratively active file to the closed file. Some patients, despite positive sputum, may be considered as having attained maximum hospital benefit. And, of course, hospitalized patients on weekend passes with the extensive liberty to associate with such susceptible groups as young children may truly be more of a hazard than some nonhospitalized patients who are effectively isolated by geographic, economic, and social conditions.

Even so, substantial numbers of the supposedly known cases undoubtedly still have tuberculosis which has not been completely inactivated. In the light of new therapeutic approaches and surgical skills, many of them

Table 7. Year of last clinical observation of nonhospitalized tuberculosis cases, 1955, New York State exclusive of New York City

have adequate space and a quiet time for doing clerical work? Are they given an adequate introduction to recordkeeping? Do they need courses in rhetoric? Is information requested that is not essential? Are field nurses aware of uses made of statistical information collected?

10. Are personnel policies at least up to the minimum standard recommended by the profes-

sional nurses' association in your community? How satisfactory are the policies about salaries, mileage rates for the use of personal cars, working hours, vacation, and leave? Can an employee who has served for many years get a 1- to 3-month leave of absence, other than for schooling, without loss of seniority or civil service status?

Program for Evaluating Heart Disease Drugs

A grant of \$575,000 to evaluate the effectiveness of drugs used in heart disease treatment was awarded Dr. Alan E. Treloar, director of research of the American Hospital Association.

The research grant, the largest of its kind ever made by the National Heart Institute of the Public Health Service, will finance a nationwide program coordinating the work of a number of research teams, as yet to be selected.

The projected large-scale study involves a testing program to determine the most effective drugs, or combinations of drugs, and dosages among the many new forms of treatment developing in the heart field. Initial emphasis will be on hypertension.

Dr. Treloar and the American Hospital Association envision the formation of an advisory board to set up the program's guiding principles and to make broad policy decisions. The board will be composed of eminent medical research workers and clinicians; it is expected to include a representative of an appropriate committee of the American Medical Association and also of the American Heart Association.

A central staff located in Chicago will include a clinician and a biostatistician who will coordinate project activities and supply administrative and biostatistical services for investigators. Each hospital and clinical research laboratory collaborating in the program will provide a representative for a technical committee. This group will serve as a means for constant communication between the research teams and will determine details of procedure.

The San Juan Basin Plan

By GEORGE MOORE, M.D., M.P.H.

IN THE EVENT of a national emergency from enemy attack, the small cities, towns, and villages of America will save the populations of many of the larger industrial cities. This statement cannot be questioned since the primary targets in the United States include most large cities with their factories and congested populations. How can the small cities and towns in rural areas save their urban neighbors? The San Juan Basin of Colorado has attempted to provide an answer.

Some 33,000 people live in the San Juan Basin, a four-corner, 12,000-square-mile area flanked by the high mountain ranges of the Rockies. The basin is central to Albuquerque

in New Mexico, to Phoenix in Arizona, to Salt Lake City in Utah, and to Denver and Pueblo in Colorado. Distances to these cities range from 200 to 500 miles. Most east-west and north-south highways in this region of the southwest converge on Durango and Cortez, Colo., the basin's largest communities. Durango has a population of 12,000, Cortez, 5,000.

In the event of enemy attack, no target in the basin would be worthy of enemy bombs, but dangers do exist. Radioactive fallout from the bombed cities may drift over the basin. Enemy saboteurs may plot destruction of vital installations. Thousands of evacuees may seek refuge in our homes and hospitals.

The danger of radioactive fallout has been met by establishing in Durango, at a cost of about \$1,000, a detection station that houses a Staplex single-volume air sampler. Manned by a team of health department personnel, the instrument is capable of detecting minute amounts of radioactivity in the air before the danger becomes serious, thus providing hours of warning. It operates on 110-volt current or by a generator.

A weather bureau official computes the fallout patterns and relays his findings to our radio

Dr. Moore, director of the San Juan Basin Health Unit, Durango, Colo., is one of three physicians appointed by the San Juan Basin Medical Society to plan for medical care in an areawide emergency. An account of Dr. Moore's experience as chief public health officer, United States Operations Mission to Nepal, 1952 to 1954, appeared in the April 1954 issue of Public Health Reports, p. 340.

station for Conelrad broadcasts on 640 and 1240 AM frequencies. If, after an attack, the team should find that fallout is a serious hazard, civil defense officials could confidently call for withdrawal toward a safer area. Mass evacuation of the basin's families can thus be a leisurely and simple procedure.

As to the second danger, we can expect that one-way bombers after their bombing runs from the north might land on the flat mesas and prairies of central and southwest States. We can also reasonably expect that airmen conversant with American customs and perhaps trained in sabotage will enter cities and towns unnoticed and mingle with the populace. Their job would be to foment panic, to set fires in forests and lumberyards, to destroy

bridges, powerplants, and oil dumps, and to contaminate water and food supplies with chemical and bacteriological agents.

A third problem, fraught with danger too, is the extent of our preparedness to receive and care for evacuees. If a city such as Albuquerque with a population of 160,000 has at least 3 hours' warning, it is expected that about 150,000 persons could be evacuated. Possibly 20,000 or more refugees will find their way northward across the desert to the mountainous San Juan Basin.

Many of these evacuees, hungry, desperate, sick, and afraid, might conceivably ransack and loot stores, gasoline pumps, and food warehouses, leaving nothing for evacuees or residents alike. And without further food and

for Small City Survival

stores for 3 weeks or more, the basin's inhabitants would themselves become victims of war. Therefore, an orderly reception of evacuees is necessary to insure help and rapid recovery for all.

The Fortress City

The survival plan is for Durango to consider itself a fortress in time of attack. At the flash of national alert, the city will go under civil defense authority, similar to martial law in many respects. All emergency teams will proceed to their stations.

Main highways leading into Durango will be barricaded with bulldozers and trucks, leaving detour routes around the city open for outside traffic as needed. All traffic within the city, except emergency and official vehicles, will be stopped. Places of business and service stations will be closed. Armed guards will be posted in front of food stores to prevent runs on supplies. School children will be sent home immediately. People will be warned to stay in their homes.

Thus, the city will be ready for attack, teams will be at their posts, and residents and workers will be at home waiting for Conelrad reports on their radios. In this period of waiting the public will ready their cars, fill tanks with stored supplies of gasoline, draw off water for storage, and prepare baskets of food. Conelrad in cooperation with the detection station will advise of fallout from bombed areas. If mass evacuation of the city is necessary, Conelrad will describe the routes to designated rendezvous points.

Reception of Evacuees

When the first evacuees arrive at Durango, they will be met at the roadblocks by the traffic control teams. If they prefer to detour the city, they will be offered a cup of coffee and a sandwich by a welfare team and then directed to follow the markers. Gas stations at each barricade will ration a few gallons of fuel, if needed, to each vehicle as long as the gasoline lasts.

For the 20,000 evacuees who prefer to stay in Durango, a different procedure is planned.

These individuals will be met at the barricades by monitoring teams who, with geiger counters and ionization chambers, will check for radioactive fallout dust. Vehicles found to be radioactive will be either left outside the barricade or motioned on toward the detour, as the occupants prefer. Vehicles found free from contamination are then screened by the police for saboteurs. Luggage and identification will be checked thoroughly before either a vehicle or person is permitted to pass the barrier. Arrangements have been made for the care of pets.

Each barricade will have a mobile first aid team led by a physician. The team will send injured and ill evacuees, by ambulance or truck, to one of three first aid centers temporarily established in the Durango public schools. The injured and sick will be treated at the first aid stations and then either transferred to a hospital or released to one of five registration centers. The healthy evacuees will be directed to a wide parking expanse where traffic teams will park the cars in an orderly fashion. Radios at the barricade will keep the teams informed of possible new dangers.

"Saboteur" found on public street by Durango police during simulated alert, July 1956.

At the parking lot, the evacuees, carrying their luggage, will board school buses waiting to shuttle them to the registration centers. The centers are to be located in public buildings central to each of five main sections in the city. They will be manned by volunteers and welfare officials. After registration, evacuees will be sent on foot, in company with boy scouts or uniformed guides, to their assigned quarters in the homes of residents. A list of available rooms is ready in anticipation of this maneuver.

In the interim, the fire department will have been waiting for emergency calls, and the police department will have stationed guards at bridges, gas depots, water works, and other vulnerable sites. Factories will have assigned men to guard industrial targets. The relative absence of street traffic will simplify the job of safeguarding people, homes, and key targets. Likewise, the detection of looters and saboteurs will be less difficult.

The next morning should see Durango intact with all evacuees received and placed. The care and conservation of what is left then begins.

Realistic Planning

A full count of evacuees and an inventory of food, clothing, gasoline, and medical supplies will determine how the city will live for the next few weeks. Health officials will check water and food for possible contamination and will try to maintain near normal services. Twice a day, volunteers and welfare and health personnel will set up food lines at the fairgrounds and at large restaurants.

For supplementary needs the granges have accumulated stores of extra supplies of canned food, fruit, potatoes, and gasoline. These will be rationed as needed. At any time, we could supply 25,000 to 30,000 pounds of milk, 25,000 head of beef cattle, 60,000 sheep, and 1,000 hogs. Flour, pinto beans, and grain are abundant. Food, therefore, should not be a problem.

If the watershed becomes contaminated with fallout, we would have enough stored water, once the reservoir is covered as planned for 1957, to last evacuees and residents 3 weeks. Water supplies have been tremendously improved this year over last by the addition of

Sheriff and civil defense aide find "bomb" under oil tank in Durango suburban area.

a new filter plant in Durango. Water during most of the year is plentiful. Most farms have wells, and water will be transported to the cities as needed. Our fast-flowing streams could in warm weather decontaminate most of the watershed within a week. Sewerage, though inadequate, also has top priority in city budgeting.

The police and firemen in Durango have been trained by former Army servicemen in many types of counter sabotage. The police and fire departments held an impressive operation alert in July 1956 together with civil defense teams, health department personnel, and amateur radio operators. The exercise simulated a realistic emergency complete with enemy agents plotting to contaminate water, incendiary fires ignited in army-type smoke pots, and time bombs planted at strategic sites (see pictures).

During an alert, auxiliary police will patrol the filter plant and reservoir, and our sanitation staff will stand by for any emergency. Continuous check will be made on the water for turbidity, changes in pH, presence of bacteriological agents, and deposits of radioactive fallout if it is a problem. The small laboratory of our health department and the technician in charge are well equipped and well qualified to make bacteriological examinations. We hope to acquire a millipore filter soon.

All of the health department staff have received special training in civil defense through courses in Denver and in Washington. They in turn have helped to train civil defense work-

ers in Durango (see program). The monitoring teams have been trained in food and water decontamination. The fluorescent antibody and phage tests for rapid bacteriological diagnosis as well as complete kits for CW (chemical warfare) sampling will be added to our program as soon as these materials are released. At present, public health defense against BW and CW attacks is not particularly effective until the specific agent is determined and after people are already sick and dying.

The San Juan Basin Health Unit now has a full year's determination of background counts on radioactive fallout. The Colorado State Health Department gave valuable assistance in calibrating the air sampler and in training health personnel in radiation detection. The weather bureau official who will chart and relay fallout reports was sent to the Sandia Corporation in New Mexico for special training.

Natural and Wartime Disasters

The survival plan will utilize every available inch of space in the hospitals as well as in auxiliary buildings. The only hospitals in the basin are the two hospitals in Durango and the hospital in Cortez. Altogether we count on having 300 hospital beds, 25 physicians, 6 dentists, 4 veterinarians, 185 first aid workers, and about 150 nurses and aides. All available nurses have been listed. If disaster strikes a nearby city, a team of 6 physicians with nurses and helpers and supplies is ready for call.

A move has been made to bring Federal Civil Defense Administration stockpiling to the basin because of the remoteness of the stockpiles in Texas and Utah and at Greeley, Colo. All hospitals are stockpiling medical supplies and rotating perishable items. Eventually, their stockpiles will hold a year's supply in advance.

Vaccines and serums are not being stockpiled to any great extent because it is not in our present plan to offer immunizations to the public at large. The health unit has been attempting to provide mass immunization through school programs. Immunization levels among school children are well over 85 percent for smallpox and diphtheria-pertussis-tetanus.

Civil Defense Training Course

San Juan Basin Health Unit

First Day

Strategic briefing of civil defense.

Effects of modern weapons. Films "Let's Face It" and "Operation Ivy."

Nuclear weapons and radiation detection instruments. Film "A Is For Atom."

Evaluation of radioactive fallout hazard.

Biomedical effects of radiation.

Chemical warfare.

Bacteriological warfare.

Films "Flash of Darkness" and "Target You."

Evening

Films "Atomic Attack" and "Frontline of Freedom."

Second Day

Civil defense analysis.

Attack warning. Film "Conelrad."

Civil defense organization.

Organization of health services, casualty care, health and medical supply program, and the improvised hospital.

Durango as a typical support area, urban analysis.

Evacuation, shelters, and cover. Films "Escape Route" and "Operation Welcome."

Rescue training. Film "Trapped."

Registration and warden services.

Police and traffic services.

In addition, the Indians in the basin are now protected with typhoid-paratyphoid vaccine.

We have tried to be realistic in planning for various types of casualties. In addition to screening evacuees for communicable disease, we have made specific provisions for isolation of disease suspects at first aid stations, for the use of churches and churchmen to help alleviate hysteria and panic, and for hospitals to set aside wards for radiation victims. Evacuees with burns, fractures, amputations, and other serious conditions are not expected in great numbers because of the basin's distance from target areas. They may be sent here later, however.

Of course, no one knows how many evacuees the basin might receive, but, for our planning, a total of 20,000 has seemed a practical number to assume. Durango, with new discoveries of oil, gas, and uranium, has become a boom town since the war. Housing is at a premium, and most new homes are ranch style and small. We would have trouble accepting more than 20,000 new people, but if we had no choice, we would use barns, rodeo facilities, and all available public buildings.

Considerable interest has been expressed in our plan. A mutual aid pact is being drawn up with Farmington, N. Mex., the first large city south on the road to Albuquerque. Farmington will detour evacuees to us as we will to them if cities to the north of Durango are bombed. Other cities in Colorado and New Mexico and even in South Dakota have shown interest in organizing similar programs. It

has been obvious that the public is worried about the future and will work enthusiastically if we lead the way and provide hope.

The basin also has an alternative emergency plan that covers the natural disasters any community might experience from train wrecks, fires, collapsed buildings, and flood. Not more than 50 casualties are expected from any one isolated incident. These we will care for by using the maximum available beds in the basin's hospitals. The hospitals are prepared, as needed, to reroute their patients and to provide morgues and extra dispensary space. Physicians have specific assignments.

Not at all phases of both plans are complete, but we trust that the ^{city} ^{of} ^{the} ^{basin} will be ready for whatever comes, natural and war disasters alike.

idea

The Personal Touch

Though approximately 400 persons receive postgraduate training in public health every year, the profession is probably losing between 600 and 700. States fortunate enough to have a reasonable number of public health workers have usually obtained the greater proportion from adjoining areas.

Our replacement needs and the additional workers needed to meet the demands of a growing population have to be viewed realistically in the light of the decreased supply of young people, brought on by the reduced birth rate from 1930 to 1941, and of the many inducements that are currently offered to them.

Industry's profits at the moment are of such magnitude in relation to

the tax structure that industries can afford to pay salaries to professional personnel for beginning employment in ranges that industries themselves recognize are greater than the employee is actually worth.

Training for public health work, usually provided from public funds because it primarily benefits the employer, has declined appreciably because of cuts in Federal grant funds. Some States have been reluctant to finance training or have been unable by law to do so. Thus, the cost of preparation is devolving upon the individuals themselves even though financial compensation, when employed, does not compare favorably with that of industry.

Since competition for personnel is so keen, I would like to suggest that there is a common need for bringing to seventh, eighth, and ninth graders some concept of the many interesting things that can be done in public health work. I would encourage maximum sensitization of this

group through whatever channels you can use to reach them. Perhaps too few of us have thought about the influence we could have by working actively in such groups as the Boy Scouts and Girl Scouts and the Hi-Y and 4-H clubs.

The most effective recruitment program I have seen for getting young ladies into a nursing school was one in which each student was given the responsibility for seeking out some worthy successor from her former high school and giving her a pledge pin.

Our recruitment programs must be personalized if they are to be effective.

—HAROLD M. GRANING, M.D., regional medical director with the Public Health Service, Region 5, Chicago, in a speech at the annual meeting of the Middle States Public Health Association, Columbus, Ohio, April 30, 1956.

technical publications

Diabetes Program Guide

PHS Publication No. 506. 72 pages. 45 cents.

State and local workers in diabetes control activities will find in this compact guide a complete presentation of the principles and procedures of community diabetes programs, starting with community resources and proceeding through prevention to case finding, education, evaluation, and research.

Emphasis is placed on working with statistical and laboratory procedures treated in some detail.

Criteria of success in diabetes programs are stated as: finding unrecognized diabetics and following them to diagnosis and treatment; helping prevent or correct obesity; helping diabetics control their condition under medical supervision; promoting the understanding of diabetes through individual and group education; and mobilizing community resources.

Included are forms and form letters, seven pages of references, and a detailed section on the cost of screening, with data on both laboratory costs and personnel.

Your Child from One to Six

Children's Bureau Publication No. 30. Revised 1956. 110 pages; illustrated. 20 cents.

This revised bulletin for parents emphasizes the mental and emotional development of children from infancy to school age.

The problem of television viewing is discussed for the first time. Other new sections point out how a child can learn to do without its mother, how to prepare a child for hospitalization, and what to tell a child who asks about death.

A comprehensive medical section tells how to handle emergencies, how

to care for a sick child, and how to prevent and recognize illness. Also provided is a complete immunization plan for children from one month of age throughout childhood.

Public Health

Merit Badge Series No. 3251. 1956. Boy Scouts of America. 66 pages; illustrated. 25 cents.

A new version of this pamphlet has been prepared in association with the Public Health Service. Designed to help Boy Scouts qualify for a merit badge, it is also an elementary introduction to basic concepts and programs of the public health profession.

Sources of Morbidity Data, Listing Number 4, 1956

PHS Publication No. 504. 1956. 74 pages.

The fourth listing of projects in the files of the Clearinghouse on Current Morbidity Statistics Projects contains descriptions of 102 projects, supplementing the 477 described in listings Nos. 1, 2, and 3 (PHS Publications Nos. 332, 399, and 459).

There are three indexes: the projects by type of data collection; the organizations and institutions participating in the projects, by State; and the principal investigators. Also included is a section of supplementary notes representing a systematic followup on projects in the previous listings that were in progress when their descriptions were received by the clearinghouse.

Because the listings of the clearinghouse are published primarily for the use of actual and potential contributors, the number of bound copies available for other distribu-

tion is limited. Tear sheets for all projects are on file, however, and these will be mailed free of charge to persons inquiring about studies of a particular type.

Federal Support for Science Students in Higher Education, 1954

National Science Foundation Publication No. 56-18. 33 pages. 30 cents.

Designed to assist in evaluating proposals for federally financed scholarships in the sciences, this report provides information on present Federal aid to college and university science students.

It shows how much of the expenditure (in the form of fellowships or otherwise) in each program went to students in the various scientific disciplines; how many career science students were assisted; which Federal agencies were involved; how the various forms of financial aid were distributed among those studying in scientific fields; and, how, among the fields of study at graduate level, the federally aided group of science students compares with the nationwide graduate student body in the sciences.

Data on students in nonscience fields are included in the aggregate only for comparison.

This section carries announcements of all new Public Health Service publications and of selected new publications on health topics prepared by other Federal Government agencies.

Publications for which prices are quoted are for sale by the Superintendent of Documents, U. S. Government Printing Office, Washington 25, D. C. Orders should be accompanied by cash, check, or money order and should fully identify the publication. Public Health Service publications which do not carry price quotations, as well as single sample copies of those for which prices are shown, can be obtained without charge from the Public Inquiries Branch, Public Health Service, Washington 25, D. C.

The Public Health Service does not supply publications issued by other agencies.

Film an Educational Aid In New Mexico's Venereal Disease Program

By BERNARD F. ROSENBLUM, M.D., M.P.H.,
and WILSON A. CORCORAN, B.A.

NEW MEXICO, in 1955, ranked sixth in reported cases of syphilis. For the young age groups, those aged 15 to 25 years, the significance of the venereal disease problem in the State is shown by the figures for that year and for 1954.

For 1955, in the age group 15 to 25, there were 212 cases of syphilis, 797 of gonorrhea, and 9 of chancroid, a total of 1,018 cases of venereal disease of all types. This was 40 percent of the total of 2,609 for the State. For 1954, the total was 2,533 cases, of which 1,108, or 44 percent, were in the group aged 15 to 25 years.

When the film, "The Invader," was shown to the staff of the New Mexico Department of Public Health, it was agreed that here was an excellent film for use in our venereal disease educational program. It was particularly suited to the age groups we wished to reach. The film was previewed at different showings by the New Mexico Parent-Teacher Association officials, the Catholic Archdiocese, and the Ministerial Alliance. All were impressed, and gave their approval and endorsement for "The Invader" to be shown to any and all groups, including public, parochial, and private schools.

A letter was sent to all local school and parent-teacher association officials telling them of the venereal disease conditions in the

Dr. Rosenblum and Mr. Corcoran of the Public Health Service Venereal Disease Program are with the New Mexico Department of Public Health, Santa Fe, N. Mex. Dr. Rosenblum is venereal disease control officer and director of the division of preventive medicine. Mr. Corcoran, a health program representative, is also assigned to that division.

This paper was presented at the First International Symposium on Venereal Diseases and the Treponematoses, Washington, D. C., May 28-June 1, 1956.

State and of the proposal to use the film, "The Invader," as an integral part of the health department's approach to the problem. The letter included a short paragraph about the contents of the film and stated that it had been previewed and unanimously approved by the State Parent-Teacher Association, the Catholic Archdiocese, and the Ministerial Alliance. It was suggested that the local parent-teacher association preview the film one evening and present it to the students the following day. A mimeographed list of the 20 questions most commonly asked about venereal disease was enclosed, for presentation to the students prior to their viewing the film. The questions were in a "true or false" form, and the student was not required to sign his name but to give only his age, sex, and grade in school. The letter requested dates and alternate dates of the parent-teacher association meetings.

Response was immediate and overwhelming. The health department was swamped with requests for the film. With only one print on loan from the Venereal Disease Program of the Public Health Service, we were in need of additional prints if we were to carry out the educational program, including the showings of "The Invader," within a 12-month period. One print was purchased, and we prevailed on the Regional Office of the Public Health Service in Dallas, Tex., to lend us another print. With three prints to be divided among a field staff of five, stationed from 200 to 300 miles apart, and the home staff of two, the three films had to be scheduled to arrive at the right time and the right place for a 2-day stay and then be sent to the next showing. Coordinating the logistics on these procedures required the combined efforts of the home and field staffs. Because mail service is often delayed in New Mexico, the prints were sent by public interstate buses. This means of transportation is widely used in New Mexico and offers more frequent and better service to remote areas than do the railroads in transporting mail and freight.

At parent-teacher association meetings, "The Invader" was presented by a member of the health department staff, usually one of the trained venereal disease investigator-interviewers or, rarely, by a public health nurse. The usual procedure was to give a 5-minute

"The Invader"

"The Invader" is a film history of syphilis from the Renaissance to the present day. The pictures and text tell of the 400-year search of scientists for a cure for syphilis, of the discovery of penicillin by Fleming in 1928, and of Mahoney's work with penicillin which resulted in the announcement in 1943 that a cure for syphilis had been found. The film also gives an account of the fight for open discussion of syphilis so that syphilitics can be reached and the "chain of infection" broken.

The informative Film Guide for Teachers and Discussion Leaders issued by the division of instruction of the Georgia Department of Education states that the film "leaves the viewer with the feeling that everyone has a part in helping to conquer syphilis" and that "the surest control of syphilis comes from the integrity within that makes a man or woman live by decent values."

introduction, usually confined to the venereal disease situation in the State, with a few words about the length of the film. The audience was told that a question period would follow the showing of the film.

The following day, when the program was presented to students, usually boys and girls together, the introduction contained the statement that syphilis is a communicable disease and that the program was being presented on that basis and not on the basis of sex education. The students were told that a question and answer period would follow the film and also that the correct answers to the 20 questions distributed earlier would be given. These question lists, which were preferably completed a day or two prior to the showing of the film, were collected by the person showing the film and later were forwarded to the State health department for tabulation. A program has yet to be completed during which the students did not ask questions, such as, "Is there any vaccine for immunity to syphilis?" and, "Can syphilis be inherited?" Almost everyone expressed the opinion that they had learned many things they had not known before, and that they had enjoyed the film.

Some "do's" and "don'ts" may be of value in presenting this film. In making final schedules, make sure that the time does not conflict with a local basketball game, baseball game, or other event, or the program will be presented to an empty hall. When the film is to be shown to several schools in the same community, a local movie theater may be used, thereby saving precious time and personnel. It is wise to carry a projector and a screen and an extra 50 feet of extension cord. Frequently, the projector provided by the school or organization has something wrong with it, and unless a workable projector is on hand, the program will be a failure. Care should be taken to rewind the film after each showing. It is embarrassing to begin a new showing of the film and have to stop and rewind it, thus losing the attention of the audience. When making arrangements to ship the film to another location, the task of transportation should be delegated to a responsible person or the film may be mislaid and delayed, disrupting the schedule.

Through these methods and efforts "The Invader" was shown to 68,229 persons during September 1955-June 1956. The film was seen by the students and faculty of public, parochial, and private junior and senior high schools; civic groups, such as PTA's and miscellaneous clubs; and military personnel, as follows:

| | High schools | Civic groups | Military personnel |
|------------------------|-----------------|-----------------|-----------------------|
| Attendance..... | 33,791 | 19,500 | 14,938 |
| Number of groups..... | 129 | 207 | 5 |
| Number of showings.... | 273 | 207 | 54 |

The following suggestions may help in planning future programs:

1. The film should be prepared with commentaries in several languages. A Spanish commentary would be useful in New Mexico.

2. If the film could be shortened it could be used advantageously for television showing. It is very difficult and expensive to get television time, and "The Invader" runs 37 minutes, making it awkward to fit the pattern of 30-minute TV programs. A 20-minute showing, with an 8-minute discussion, would make a 30-minute program with 2 minutes for the announcer.

Because of its success in New Mexico, we recommend showing "The Invader" as an integral part of a venereal disease education program.

Contributions of Premarital and Prenatal Blood Testing in Syphilis Control

By HAROLD J. MAGNUSON, M.D., JAMES F. DONOHUE, M.P.H., JOHANNES STUART, Ph.D.,
and GERALDINE A. GLEESON, A.B.

MUCH OF THE PROGRESS in syphilis control during recent years has been accomplished through the cooperative efforts of the national venereal disease control program, State and local health departments, and various private agencies. The control measures and techniques used by these health agencies form such a closely integrated system that it is difficult to break down the contributions of certain components or to evaluate the efficiency of specific control measures. However, in this report two segments of the program, namely, premarital and prenatal blood-testing legislation, have been isolated, and an attempt has been made to measure the specific accomplishments of required blood testing.

Aside from the case-finding aspects of required blood-testing programs, the primary purpose of premarital and prenatal blood testing is to preserve the health and welfare of the family unit by preventing the transmission of

syphilis to marital partners and by protecting unborn children from infection with congenital syphilis. Such blood testing also has its educative values.

One of the most immediate results of effective premarital and prenatal blood-testing legislation should be reduction of infant mortality due to syphilis. But since there has been a general downward trend in infant mortality from syphilis during the past 20 years, it is difficult to determine by observation alone whether this reduction in rates would have occurred regardless of blood-testing legislation, or whether there is a definite relationship between the two factors.

In an attempt to distinguish between the reduction in infant mortality due to blood-testing legislation and the general downward trend in infant mortality, composite rates per 1,000 live births for infant deaths due to syphilis were computed for States having prenatal blood-testing laws during 3 years prior to the year the law became effective. Assuming these three yearly rates to be representative of the general trend of infant mortality due to syphilis immediately preceding the passage of the law, a straight line trend ($a + bx$) was fitted to these rates and then extended through 5 years following prenatal legislation. Confidence limits at the 1 percent level of significance were set up about this extended line to allow for chance variation. The actual observed rates were plotted for the 5 years.

Figure 1 shows that the observed infant mortality rates for all years are significantly lower

Mr. Donohue and Dr. Stuart are chief statistician and program management officer, respectively, Venereal Disease Program, Public Health Service. Dr. Magnuson, chief of the Occupational Health Program, and Mrs. Gleeson, a statistician with the Air Pollution Medical Program, were formerly with the Venereal Disease Program, Dr. Magnuson as chief of the Operational Research Section and Mrs. Gleeson as a statistician.

This paper was presented at the Third Biennial Planning Conference of the Association of State and Territorial Health Directors, Washington, D. C., May 25, 1956.

Figure 1. Composite rate of infant mortality due to syphilis in 42 States before and after enactment of prenatal blood-testing law.

than the expected trend based on rates prior to blood-testing legislation. As a specific contribution to syphilis control, it is estimated that through the effectiveness of prenatal blood testing 1,000 infant deaths from syphilis were prevented in 42 States during the first 5 years following enactment of the law. Since 30 of the 42 States with prenatal blood-testing laws had enacted these laws during 1943, or earlier, the interval represented in the 5-year period is largely coincident with the war years and the immediate postwar years. This reduction in infant mortality due to syphilis becomes even more remarkable in view of the fact that it was accomplished during a period when infections syphilis case rates among civilians were at a peak and before penicillin became available for civilian use. This points up the vital importance of the operation of required blood-testing programs before, during, and after national crises which boost the rate of venereal disease infection.

The procedure used in evaluating the effectiveness of prenatal blood testing was also

used in examining the efficiency of premarital blood testing. Figure 2 shows that, except for a longer time interval, rates are essentially the same as would be expected before the reduction in infant mortality rates became readily apparent.

Prenatal Testing

To investigate the effectiveness of prenatal blood testing in individual States, the trend established by pre-law rates was related to post-law rates in each of the 42 States having prenatal blood-testing legislation. The results were as follows:

1. Fourteen States had an upward trend in infant mortality from syphilis during the 3 years preceding the effective date of the prenatal blood-testing law. After the passage of the law, all of these States had a downward trend in infant mortality from syphilis and experienced significantly lower rates than expected during 5 years following prenatal blood-testing legislation.

2. Two States with a steady level of infant

mortality due to syphilis during the 3 years preceding passage of the prenatal blood-testing law had significantly lower rates than expected during the subsequent 5 years.

3. Twenty-six States had a downward trend of infant mortality due to syphilis during the 3 years preceding prenatal blood-testing legislation. In all of these States the trend in infant mortality due to syphilis continued downward in the years immediately following legislation, in 7 at a faster pace than expected; in 6 at approximately the pace expected; and in 13 at a slower pace than expected.

As an example of the enactment of a prenatal blood-testing law resulting in decreased infant mortality due to syphilis, the observed rates in relation to expected trend are shown in figure 3 for the State of New Mexico. The significant decrease noted during the years 1950-53, following the passage of the law in 1949, is even more remarkable in view of the fact that New Mexico has for some years had the highest rate of infant mortality from all causes in the United States.

It might be asked if the accelerated decrease in infant mortality due to syphilis was confined to States with required prenatal blood-testing legislation or if States without such legislation experienced a comparable reduction in infant mortality rates. Since there is no date of law enactment to use as a point of reference in establishing an expected trend of infant mortality from syphilis in States without prenatal or premarital blood-testing laws, the selection of a year from which to project such a trend becomes fairly subjective. However, the observed trend line for areas without such legislation shows a gradual reduction in infant mortality from syphilis from 1936 to 1950, but how much more of a reduction would have occurred during these years if blood-testing legislation had been in operation is a matter of conjecture.

In addition to the reduction in infant mortality due to syphilis there is evidence to indicate that prenatal blood testing makes a definite contribution to the control of infant mortality from all causes. Presumably this is accomplished by bringing many expectant mothers to prenatal

Figure 2. Composite rate of infant mortality due to syphilis in 40 States before and after enactment of premarital blood-testing law.

Figure 3. Rate of infant mortality due to syphilis in New Mexico before and after enactment of prenatal blood-testing law.

care which they probably would not obtain otherwise.

For the years 1951-53 the total infant mortality rates were significantly lower in the group of States with prenatal blood-testing laws. Since the States without these laws are not those with unreasonably high infant mortality from causes other than syphilis, it seems reasonable to assume that the lower infant mortality in States with prenatal blood-testing laws may have been due at least in part to increased

prenatal care incident to the required blood-testing program.

Race Distribution

Race distribution is, of course, a very real factor in measuring infant mortality. To determine the results of prenatal blood testing, specific for race, we have prepared some comparative material on areas with and without the law with varying percentages of white population. The 7 areas without prenatal

laws (6 States and the District of Columbia) happen to cluster in 3 geographic areas where white births comprise the following percentages of total births: 63 percent in Alabama, Tennessee, and Mississippi; 75 percent in the District of Columbia and Maryland; and 98 percent in Minnesota and Wisconsin. Total infant mortality in neighboring States with a prenatal blood-testing law and of a comparable proportion of white births was compared with the total infant mortality in these three areas. In every case, regardless of race distribution, the infant mortality rate among the white population was lower in 1953 in States with the prenatal blood-testing law than in States without such a law. Conversely, in all instances, the nonwhite infant mortality rate was higher in States with the prenatal blood-testing law than in States without this law, with the differential becoming greater as the number of nonwhites in the population decreased.

There may, of course, be a number of factors contributing to this paradox among nonwhites. One factor is the administration of the law. This was borne out by a study of New York City birth certificates which asked whether a prenatal blood test had been made (see table).

Results of a study on prenatal care in New York City, 1951

| Race | Number of births | Late or no prenatal STS | |
|-------------------|------------------|-------------------------|---------|
| | | Number | Percent |
| White..... | 4, 905 | 639 | 13. 0 |
| Puerto Rican..... | 521 | 228 | 43. 8 |
| Nonwhite..... | 1, 138 | 441 | 38. 8 |

From birth certificate data it was found that in 13 percent of the white births studied, the mother either had no serologic test for syphilis (STS) or had had an STS only during the last trimester of pregnancy, as compared with 44 percent among Puerto Rican and 39 percent among nonwhite pregnant women. If only 60 percent of nonwhite pregnant women are being adequately tested for syphilis in New York City, where a prenatal law has been in effect since 1938 and where medical facilities are known to be available, there is reason to believe

that administration of the prenatal law is even less effective in areas where prenatal care is less adequate. With higher percentages of nonwhites in an area, the administration of the law becomes less effective for this group.

Penicillin Therapy

Another factor which adds to the difficulty of evaluating prenatal blood testing is penicillin therapy. This has undoubtedly affected, even to the point of destroying trend comparability, the two measures we use to estimate the incidence of congenital syphilis, namely, reported number of cases and infant mortality due to syphilis. With penicillin readily available and carrying little therapeutic risk, many physicians have adopted the policy, in cases of doubtful diagnosis, of treating infants on a prophylactic basis. Since these cases are not diagnosed, they are not included in the congenital syphilis case rate. On the other hand, treatment of syphilitic babies with penicillin has been so successful that infant mortality due to syphilis is no longer comparable to this rate during the arsenical-bismuth era. Thus, the reductions in the incidence of congenital syphilis may be due, for the most part, to therapy rather than to the actual prevention of cases. Very recently, with the alarm aroused by increased reactions to penicillin, this therapy is in many cases being withheld, which complicates the trend pictures even more, but at the same time points up the need for prenatal screening.

Congenital Syphilis

Another facet of the evaluation of required blood-testing programs centers on the difficulty of diagnosing congenital syphilis. In infants, there may be no physical signs of the disease, and the serologic test is sometimes negative until 3 or 4 months of age. In present-day venereal disease control programs, many years pass before it is certain that all children at risk have been screened for congenital syphilis. Mass blood-testing programs are designed for those who have reached early adulthood, and we know from experience that very few cases of congenital syphilis are found in blood-testing surveys. Hence, the child with congenital syphilis often remains undiscovered and un-

treated until he enters school, applies for a job, enters military service, or plans to marry. An effective prenatal blood-testing law will protect him from infection before birth. For instance, in the fiscal year 1955, 4.8 percent of the reported cases of congenital syphilis were in infants less than 1 year old at time of discovery of syphilis, 2.2 percent in children aged 1-4 years, 8.1 percent in children aged 5-9, and 85 percent were in children 10 years old or older. In numbers, this means that 4,700 of the 5,515 patients with congenital syphilis reported in fiscal year 1955 were approaching or had reached adulthood before detection of the disease. This number, added to the undiscovered reservoir of cases still in the population, represents, in a measure, the past failures of prenatal blood testing and points up the need for more effective administration of the law.

Premarital Testing

Reactivity rates in premarital blood testing have not declined in the period 1951-54, the only period for which we have data available. This maintained level of reactivity indicates that whatever reasons there may have been for the original enactment of the laws, these reasons may still be valid. The argument may be raised that premarital blood testing has not discovered an appreciable number of cases of early syphilis; however, it must be kept in mind that premarital blood testing was not expected to find much lesion syphilis. Conservative estimates indicate that 12,000 to 13,000 previously untreated syphilitic persons are found annually through premarital blood testing. Because of the age-interval of candidates for premarital blood testing, most of the cases of syphilis detected are early latent. Our current epidemiological indexes indicate that each person diagnosed with early latent syphilis names, on the average, 2 contacts, and that 115 cases of syphilis per 1,000 of these contacts examined are found as a result of contact interviewing.

Required blood testing has general health educational value. The very fact that it is required by law is convincing proof to many of the efficacy of such a procedure. Very few people submit to premarital or prenatal blood

testing without some notion of why they are being tested. Premarital blood testing, which in most States is incorporated as part of a physical examination, offers the physician opportunities to find lesion syphilis, to do effective case finding of other diseases, and, in some cases, to provide sex education and marriage counseling. Premarital and prenatal blood testing in the control of syphilis are analogous to preventive medicine in other diseases. Since preventive medicine is the very essence of public health, blood-testing legislation is desirable.

As an index of prevalence of syphilis, the need for required blood testing continues. Perhaps of greater importance than as a statistical measure of control, required blood testing screens a segment of the population in which the incidence of early syphilis must be kept at a minimum if venereal disease control is to be maintained. Furthermore, the value of prenatal and premarital blood-testing laws must be measured against the number of cases of syphilis prevented by the existence of these laws as well as in terms of the cases found by their operation.

As a possible example of this dual evaluation of blood-testing laws, 100 cases of early syphilis detected among 100,000 persons examined premaritally would result in an infection rate of only 1 case per 1,000 examined. However, in terms of prevention, the 100 additional new infections which could have developed in prospective marital partners, plus the likely congenital infections in offspring of these marital unions, increase this rate to new proportions. By adding to these infections the previous contacts from which the initial 100 infections were acquired, 1 case actually detected among each 1,000 premarital examinees should be increased to perhaps 5 cases (assuming 2 offspring to each union) to measure more accurately the efficiency of premarital epidemiology and case finding.

Summary

Premarital and prenatal blood-testing legislation, when properly administered, contributes to venereal disease control by (a) detecting and bringing or returning to treatment persons with syphilis, (b) preventing the transmission of syphilis to marital partners, (c) protecting un-

born children from congenital infection, (d) reducing morbidity and mortality due to syphilis and to other causes among infants by encouraging prenatal care, and (e) providing opportunities for general health education, sex education, and marriage counseling. Despite the accomplishments of required blood-testing

programs during recent years, there remains much to be done toward the prevention and control of congenital syphilis. As long as cases of congenital syphilitic infection continue to be found in our population, there is a definite need for strict enforcement of blood-testing legislation.

Revised Statement of Rheumatic Fever Prevention

Revised recommendations for preventing first and repeat attacks of rheumatic fever are incorporated in a new edition of the American Heart Association's statement on Prevention of Rheumatic Fever and Bacterial Endocarditis Through Control of Streptococcal Infections.

This is the second revision of the statement, prepared by the AHA Committee on Prevention of Rheumatic Fever and Bacterial Endocarditis to keep pace with the progressively growing body of knowledge and experience in this field. The committee points out that no recommendations can be considered final at this time. Revisions and changes will be made as new knowledge may indicate.

Principal Changes

Following are the principal changes in the recommendations:

1. Greater emphasis is placed on the value of throat cultures in diagnosing streptococcal infections with a view to stimulating an increased use of cultures, particularly when clinical manifestations alone are inconclusive.

2. The recommended duration of prophylaxis has been qualified. The committee reaffirms its view that continuous prophylaxis should be maintained indefinitely for known rheumatic subjects, but it recognizes that some physicians may wish to make exceptions in certain of their adult patients, particularly those without heart disease who have had no rheumatic attacks for many years.

3. Monthly injection of 1,200,000 units of benzathine penicillin G intramuscularly is now listed first among prophylactic methods. The committee also indicates that it is preferable, if oral penicillin is chosen as the method of prophylaxis, to prescribe 200,000-250,000 units twice daily, rather than once,

providing an additional safeguard against breakthroughs which have been reported with the smaller dosage.

Bacterial Endocarditis Prophylaxis

Also revised in the statement are the recommended dosages for prophylaxis against bacterial endocarditis in patients with rheumatic or congenital heart disease who are obliged to undergo such surgical procedures as dental extractions and tonsillectomies. Emphasizing that the dosage regimens used for long-term prophylaxis of streptococcal infections are inadequate for this purpose, the committee recommends that high blood levels of penicillin be maintained for several days (rather than, as previously stated, on the day of operation alone) to prevent organisms from lodging in the heart valves during the period of transient bacteremia.

In general, the combined oral and parenteral route of administration is preferred, as follows: oral penicillin (200,000-250,000 units four times a day) for the 2 days before and the 2 days after surgery; the same dosage of oral penicillin on the day of surgery plus 600,000 units of aqueous penicillin with 600,000 units of procaine penicillin shortly before operation. Alternative recommendations are included for situations in which injection is not feasible or penicillin is contraindicated.

The revised statement appears in the December 1956 issue of *Modern Concepts of Cardiovascular Disease* and in the January 1957 issue of *Circulation*. An outline of a recommended method for culturing beta hemolytic streptococci from the throat is also being made available by the association and may be obtained from local heart associations or the American Heart Association, 44 East 23d Street, New York 10, N. Y.

Serology Control Program Of the Venereal Disease Research Laboratory

By AD HARRIS
and HILFRED N. BOSSAK, B.S.

THE SEROLOGY CONTROL program of the Venereal Disease Research Laboratory was evolved to assist State laboratories in attaining and maintaining a high level of efficiency in serologic testing. Through these State laboratories, the testing efficiency of all laboratories of this country performing serologic tests for syphilis may be favorably affected. This program has nine integrated segments, each of which is of little value as a separate entity, but which, collectively, have been effective in reaching the objective with a minimal expenditure of time and money. The serology control program has also served as a pattern of operation used by several States as a service to the laboratories within their jurisdictions. Available to the central laboratories of the 48 States, the District of Columbia, Alaska, Hawaii, Puerto Rico, and the Virgin Islands, the services of the program include:

Providing a laboratory manual prepared by the staff of the Venereal Disease Research Laboratory.

Providing reference-standard serologic reagents prepared by the staff of the Venereal Disease Research Laboratory.

Inspecting laboratory serology control programs.

Conducting scheduled training courses.

Conducting field refresher training courses or workshops.

Standardizing and supplying dehydrated control serum.

Conducting hemispherewide serologic evaluation studies on a continuing basis.

Mr. Harris is director of and Mr. Bossak is a bacteriologist with the Venereal Disease Research Laboratory, Public Health Service, Chamblee, Ga. Their paper was presented at the First International Symposium on Venereal Diseases and the Treponematoses, Washington, D.C., May 28-June 1, 1956.

Participating as a control or co-control in intrastate serologic evaluation studies.

Offering a *Treponema pallidum* immobilization (TPI) testing service, nationwide, through the State and Territorial laboratories.

Manual of Serologic Tests

A Manual of Serologic Tests for Syphilis has been prepared with the assistance of the authors of the tests and is revised at appropriate intervals. The manual contains general information about equipment; cleaning and care of glassware, antigens, and other reagents used in serologic tests; the effect of room temperature on test results; reporting of serologic test results; and laboratory control of test performances. Technique outlines, including recommendations for equipment, glassware, reagents, and step-by-step procedure for APHA reference, Hinton, Kahn, Kline, Kolmer, Mazzini, Rein-Bossak, and VDRL tests, are contained in the 1955 edition (1). Instructions are given in the appendix for the collection and preservation of sheep red cells, preparation and preservation of complement, use of merthiolate as a bacteriostat for spinal fluid, and a recommended method for quantitative determination of spinal fluid protein. This manual has been revised at approximately 5-year intervals in order to stay abreast of acceptable changes in the field of serology. The 1955 edition is the latest revision.

Services to Laboratories

Standardized antigens and other reagents for the tests listed in the Manual of Serologic Tests for Syphilis are prepared and made available for check-testing purposes to commercial or State laboratories that manufacture or purchase these reagents. During past years, the older type, lipoidal antigens were standardized and distributed for use in check-testing but this activity is now confined to the cardiolipin-type antigens. Verification testing of antigens prepared by State laboratories is also done on request. Agreements have been reached under which samples of VDRL antigen are submitted to the Venereal Disease Research Laboratory for check-testing and approval before sale by commercial laboratories in this country.

State laboratories are visited on request for consultation and for reviewing their serology program (testing, laboratory control, training, and laboratory visitation). Written reports of observations, commendations, and recommended changes, if any, are submitted to the State laboratory director and the State health officer. This service will be more fully described in a later paper.

Training Courses

Training courses are regularly scheduled at the Venereal Disease Research Laboratory. Nine 2-week courses were scheduled during the fiscal year 1956; 10 courses were held. Applications from this country for these 2-week courses must be signed by the State health officer or the State laboratory director, unless the applicant is an employee of the Public Health Service, in which case the application must be approved by the medical officer in charge of the laboratory where the applicant is employed. Trainees are accepted from Armed Forces installations in this country and from the World Health Organization, the Pan-American Sanitary Bureau, and employees of central laboratories in other countries. Schedules of courses for each fiscal year are distributed before July 1, and reservations are made as soon as applications are received. Application lists are closed 1 month before the dates the courses are to start.

Five courses titled "Serology of Syphilis" were scheduled for the fiscal year beginning July 1956. These courses provide refresher training to senior operating personnel of State and Public Health Service laboratories. They are composed of lecture, demonstration, and participation periods covering the most widely used American methods for the serodiagnosis of syphilis, with references to latest developments in this field.

The two courses in management and control of syphilis serology by the regional laboratory are designed for assistant laboratory directors and senior laboratory staff members and include review of interlaboratory serologic evaluation studies, laboratory inspection procedures, demonstration of antigen check-testing and standardization, and preparation of control serum.

Courses about tests for syphilis using the *Treponema pallidum* include lectures, demonstration of and class participation in the immobilization (TPI), agglutination (TPA), complement-fixation (TPCF), immune-adherence (TPIA), and other tests which use the virulent *Treponema pallidum* as an antigen source. The complexity of these tests requires that these classes be limited to small groups, so it has been necessary to schedule additional classes when large numbers of qualified applicants have applied. Applicants for these courses should have had adequate experience in the field of serology and be in supervisory positions.

Field refresher training courses are also held in cooperation with State department of health laboratories. On-the-job training is also accomplished during visits to Public Health Service laboratory facilities.

Control Serum

Dehydrated control serum for serologic tests for syphilis is offered to the State laboratories and to Public Health Service laboratories on a continuing basis. Twenty-six ampules of serum, considered to be a 6 months' supply when used at the rate of one ampule per week, are sent with a protocol showing the reactivity of each lot of serum in all of the tests performed at the Venereal Disease Research Laboratory. Continuous use of this control serum will allow the laboratories to determine the relative reactivity of their tests as compared with the same tests performed at the Venereal Disease Research Laboratory and, secondly, will show whether the reactivity of their tests is remaining at a constant level or is varying from day to day. The laboratories that use this serum do not report their findings to the Venereal Disease Research Laboratory, since this is not considered to be an evaluation service.

Serologic Evaluation Studies

The Public Health Service Serologic Evaluation Study is presently being conducted by distributing 20 samples of prepared sterile serum to each of 62 participating laboratories in each of 10 months of the fiscal year. During

the remaining 2 months, all reports are tabulated and an analysis of comparative results is issued. Laboratories participating in this study during the fiscal year 1956 included the central laboratories of the 48 States, the District of Columbia, Alaska, Puerto Rico, Hawaii, Mexico, and Canada, plus the Kahn, Kline, Kohner, Hinton, Rein, and Mazzini laboratories and the Venereal Disease Research Laboratory. This type of serologic evaluation study produces data that may be used to ascertain relative efficiency of many laboratory performances of each type or kind of test as compared with the test-author results. In order to make available to the participating laboratories some comparative results before the yearly report is analyzed, a report of the results obtained at the Venereal Disease Research Laboratory each month, with all procedures, is sent to all participating laboratories as soon as their monthly report is received.

A similar, but smaller, serologic evaluation study is presently being conducted for the laboratories of Public Health Service facilities. In this study, 10 samples of prepared serum will be sent monthly for 5 months of this fiscal year to each of 26 Public Health Service laboratories. A report of the results obtained with the VDRL slide test and the Kohner test at the Venereal Disease Research Laboratory is returned to the laboratories participating in this study as soon as their monthly reports are received.

Use of VDRL Services

The central laboratories of all 48 States, the District of Columbia, Alaska, Hawaii, Puerto Rico, and the Virgin Islands have received one or more of the services referred to in this report during the recent past. In the calendar year

1955, these laboratories utilized the services and control functions of the Venereal Disease Research Laboratory 264 times, in addition to submitting 2,875 serums for TPI testing. Additional services were given to the central laboratories of other countries either directly or through the function of the Venereal Disease Research Laboratory as a reference laboratory for the World Health Organization.

TPI Testing Service

The *Treponema pallidum* immobilization (TPI) test has been offered since January 1955 as an additional reference service, on a nationwide basis, through the laboratories of State health departments, by the Venereal Disease Research Laboratory. Criteria for acceptance of specimens for this testing are stipulated. Blood specimens are sent to State laboratories, where sterile serum is separated and forwarded to the Venereal Disease Research Laboratory. Each specimen of serum must be accompanied by a completed clinical data sheet containing statements about evidence or history of treponematosi; syphilis in the family; other venereal diseases; record of known STS; diseases other than treponematosi especially those presumed to elicit nonspecific reactions in STS; and the opinion of the attending physician regarding present diagnosis. Reports of TPI tests are sent to the respective State laboratories for forwarding to the submitting physician. During the first months of 1956, requests for this service were received at the rate of approximately 100 per week.

Occupational Health on Farms

By HENRY N. DOYLE

HEALTH AGENCIES have many as yet undischarged responsibilities toward rural Americans. To comprehend the responsibilities of official agencies for occupational health on farms, it is useful to grasp the extent of industrialization of American agriculture.

The population of the United States in 1910 was 92 million. Today, it is 166 million, an increase of 80 percent. In 1910 there were 322 million acres of cropland. Today there are 350 million acres of cropland, an increase of only 9 percent. Yet, this acreage produces more than enough food for our expanded population. It is estimated that 310 million acres will supply our 1960 population, thanks to the increase in productivity per acre. Improved soil management, such as erosion control and the use of fertilizers and other agricultural chemicals, including pesticides and weedkillers, have contributed part of this gain. Power machinery has increased the farmer's capacity to plow, sow, harvest, and manage livestock. Furthermore, market crops now grow on about 75 million acres formerly used to grow feed for the horses and mules which have been replaced by power machines.

Mechanization has made it possible for farms to produce more than enough for our present needs through the efforts of only 6,500,000 farm workers, or 11 percent of our working popu-

lation, whereas in 1910, 11,600,000, or 31 percent, were employed in agriculture.

The number of American farms in 1954 was 5,425,000, as compared with about 6,600,000 in 1910. More important, half of our present farms produce nine-tenths of the crops. This concentration offers a striking parallel to many industries in which a small number of large companies account for a high percentage of the total production.

Even as large manufacturing concerns tend, with large-scale operations, to employ the latest advances in mechanization, so, and frequently to a greater degree, large farms tend to employ mechanical equipment. The capital investment associated with many of the new mechanical farm devices often runs to a sum which is not economical for a single-family farm.

Some idea of how mechanization has progressed in farming may be obtained from United States Department of Agriculture statistics which reveal that between 1941 and 1952 the number of tractors increased from 1.7 million to 4.4 million (159 percent), the number of grain combines from 225,000 to 940,000 (318 percent), and the number of mechanical corn-pickers from 120,000 to 635,000 (429 percent). The increase of total power on American farms during that period exceeded 70 percent. Farm output per man now has approximately doubled in the 15 years since Pearl Harbor.

Agricultural changes during the past generation, therefore, have come to create new working conditions even as industrialization changed working conditions in mines and mills.

How do these new conditions affect the health and safety of farm workers? Farming is intrinsically hazardous. Injuries have always been frequent on farms. Although statistical

Mr. Doyle is assistant chief of the Occupational Health Program, Public Health Service. His paper and the summaries of the papers on silicosis and X-ray exposure (p. 149) are based on talks delivered to the American Conference of Governmental Industrial Hygienists, Philadelphia, April 21-24, 1956.

evidence is lacking, experience has led us to expect many injuries from the handling of farm horses. A limited survey in one county within the past 6 months showed that 8 out of 29 recent accidents were associated with horses. Even with mechanization, farmers tend to keep a few horses. Of 44 farms visited in this survey, 36 had at least one horse. The total was 182.

Other farm animals also, particularly bulls, present hazards to farm hands. Injuries from the use of sharp or heavy tools or the stress of heavy lifting also are common farm afflictions, frequently resulting in chronic conditions, herniation, paraplegia, or impairment of vision.

The danger of infections from injuries incurred on the farm must be considered much greater than that in industry. This danger is heightened by the nature of the working environment, the inaccessibility of first-aid facilities, and the absence of interest in giving prompt care to minor wounds and other dermatological conditions. The prevalence of the tetanus hazard on farms is well recognized by physicians, but other organisms also must be considered.

A number of bacterial diseases are associated with agricultural work. Brucellosis, or undulant fever, is thought to be the most common one, but reliable statistics are lacking. It is not likely that all brucellosis is correctly diagnosed or that all diagnosed cases are reported. One factor contributing to the incidence of brucellosis is that rather than call upon a veterinarian, many farmers themselves vaccinate cattle and thereby risk accidental infection. Other diseases of significance on farms include anthrax, erysipeloid, leptospirosis, tularemia, bovine tuberculosis, and various forms of salmonellosis.

By occupation, the farmer is exposed also to viral and rickettsial diseases, including equine encephalomyelitis, psittacosis, Q fever, and Rocky Mountain spotted fever. There is a long list of mycotic diseases, of which actinomycosis and histoplasmosis are examples. A number of parasitic diseases also are potential farm hazards.

Moving from these biological hazards to physical agents, we find that farm work involves exposure to extremes of temperature,

both high and low. Heat exhaustion and heat stroke undoubtedly affect many farm workers. Another condition of possible significance is skin cancer, produced by prolonged exposure to the sun's rays.

The increased use of machines has brought a whole group of hazards new to agriculture. Noise exposures, for example, may now be sufficient to affect the hearing of farmhands who operate machines for extended periods. When more is learned about the problem of vibration, it may also be found to have adverse health effects on agricultural workers. Maintenance and repair work on farm machinery introduce hazards associated with welding.

Accidents incurred in the use of farm machinery represent one of the major categories of farm hazards. Accident rates in agriculture are far above industry as a whole. In 1954 only the mining and construction industries had higher death rates: Agriculture had 60 fatal work accidents per 100,000 (a total of 3,800) as compared with a rate of 25 per 100,000 for all industries. The injury rate, according to the National Safety Council, was 4,930 per 100,000 as compared with 3,240 per 100,000 for all industries.

Hazard From Chemicals

In addition to biological and physical hazards, the industrial hygienist who looks at present-day farming is struck forcibly by the number of toxic chemicals in use. Although many of these are soil conditioners and fertilizers involving little hazard, the majority are insecticides, fungicides, rodenticides, nematocides, and weedkillers which are employed specifically because of their toxic properties. While some are comparatively safe, nearly all present some degree of danger, and some must be classified as extremely hazardous. In particular, the heavy metals, such as lead, arsenic, and mercury, the halogenated hydrocarbons, and the organic phosphates present serious potential dangers to the people using them and sometimes to others working or living in the vicinity.

In dealing with industrial exposure to hazardous materials, we frequently express the view that any material, regardless of toxicity, can be used safely provided that proper

control measures are employed. The same philosophy might be applied to agriculture, but assurance of proper control measures is harder to obtain, at least at the present time. The reasons are apparent. Industrial operations are usually performed in a fixed location where exhaust ventilation or other suitable control methods are feasible. Industry has been subjected to fairly extensive and intensive educational programs on health and safety for at least a generation. Large companies usually have full-time safety and medical departments alert to potential dangers. Furthermore, personnel of insurance carriers and official agencies make frequent visits to industrial plants to check for possible hazards.

On the other hand, agricultural workers generally have little idea of the hazards of handling and applying powerful chemicals. Although most chemicals of this type carry warnings on the container labels, the tendency is to pay little or no attention to the labels, particularly if a material has been used previously without untoward incident.

Moreover, the methods of application are almost as varied as the materials used. Many of these methods present dangers that would not be tolerated in manufacturing establishments. For example, the application of fumigants such as carbon tetrachloride in connection with grain storage may employ techniques that would horrify an industrial hygienist. A recent farm survey observed workers tying handkerchiefs over their faces to protect themselves from heavy concentrations of carbon tetrachloride.

The hazards of farm life are not to be ignored. And they are not ignored although much remains to be done to protect the farmer's health.

Health Services for Farm Workers

Occupational health programs are conducted in official agencies either because of laws specifically concerning industrial working conditions or because of broad powers regarding the protection of health. Virtually all such programs were introduced to cope primarily with problems associated with manufacturing, and, sometimes, also mining. Few

of them gave much thought initially to the farm worker. In recent years, certain State officials have devoted attention to specific farm problems brought to their attention. For example, in Florida, in 1952 there were 46 claims for parathion poisoning filed; in 1953, there were 45. The Florida State division of industrial hygiene has since conducted an educational campaign among citrus grove and truck garden owners on the hazards of insecticides and preventive measures.

Also, California has conducted investigations of the high incidence of occupational disease among its agricultural workers. In 1954, of 23,101 reports of occupational disease in California, 3,143 (13.6 percent) were for agricultural workers.

In addition to purely occupational influences, the health of many farm workers is affected by environmental factors that are much less significant among present-day urban workers. Farm laborers, especially migrant workers, sometimes must live where housing and sanitation levels are far below those now considered as acceptable or safe. Large numbers of workers move from one State to another in pursuit of peak season farm work, and they stop at places where waste disposal is primitive, where water supplies are of questionable quality, where food spoilage is difficult to prevent, and where protection against flies and other disease carriers is absent. With this mobile population, numbering more than the citizens of several States, public health considerations demand far more than control of the traditional occupational diseases. In addition to basic sanitation, there must be answers to knotty questions of medical care for individuals not eligible for service available to permanent residents. Otherwise, it is reasonable to expect that transient workers will be permitted to carry communicable disease to every community that summons their services.

While rural health services can use all available community resources, occupational health personnel must not overlook their special responsibility. Industrial hygienists, in checking the working environment in factories and mines, are also concerned with the water supply, washing facilities, waste disposal, and food sanitation. Nor should they neglect these

points with respect to farm work, or, for that matter, in other situations where rural workers are housed temporarily, as in construction camps. Since such responsibilities also rest upon other personnel in State and local health agencies, policies for the best utilization of available man-hours must be developed to meet the individual situation. It is important, however, to recognize the place of environmental and medical care services in the occupational conditions of agricultural workers.

South Dakota and Iowa Programs

As stated before, a number of State occupational health officials have concerned themselves, to a limited extent, with specific or selected health needs of agricultural workers. To the best of our knowledge, however, no agency has ever considered the total need, with the objective of ascertaining the extent and severity of health problems on the farms of its State. This approach, which has been applied effectively by the States in planning logical and sustained programs for the improvement of worker health in industry, must now be used in agriculture if we are successfully to protect and improve the health of the farm family and its helpers.

The first stirring of activity in this direction came in 1955, when the South Dakota Department of Public Health requested assistance in planning an occupational health program for the State. In response to this request, the Public Health Service suggested that the program be developed to give industry and agriculture equal consideration from the start. To help develop such a program, the Occupational Health Program of the Public Health Service assigned a veterinarian to South Dakota in September 1955. Through this project it is hoped to evaluate the effectiveness of certain

survey techniques and to develop useful information regarding occupational health problems and methods for their attack.

Coincidentally, during 1955 the State University of Iowa Medical School established an Institute of Agricultural Health which will study similar questions in Iowa.

It is significant, we believe, that these related projects were independently conceived and started at this time. Although the existence of health and safety hazards on the farm has been recognized by public health authorities for some years, the South Dakota and Iowa programs represent the first positive steps taken toward a comprehensive approach to the problem.

While some findings from these two States may become available relatively soon, other States need not wait for them before taking stock of the adequacy of their activities with respect to this particular segment of the employed population. Indeed, because of variations in crops, climate, soil, and other factors, problems will be found to differ in each locality, and all States can contribute appreciably to scientific knowledge while carrying out a public health activity of real merit.

The subjects which need exploration are numerous. Study needs to be made of the toxicology and proper application of chemicals, of the safe use of mechanized equipment, of the general health status of agricultural workers as compared with the rest of the population, of the effectiveness of educational measures, and of the availability of health resources.

This is a new and complex field confronting the industrial hygienist. Occupational health needs on the farm may not be readily anticipated, but in every State where agriculture is a significant industry, an earnest beginning should be made to meet this public health responsibility.

Pediatricians Receive Low X-ray Doses

PHR X-rays as an occupational hazard of physicians have been associated with a relatively high incidence of leukemia in the medical profession.

In an effort to measure the probable routine exposure to radiation of certain specialists in private practice (in contrast to the number of such studies that have been pursued in hospitals), representatives of the Public Health Service arranged to survey the offices of 55 pediatricians in Hamilton County, Ohio.

All but 10 of the physicians used X-ray equipment, mainly for fluoroscopy. The survey was confined to this use. Instruments measured the time the fluoroscopes were in operation for 2 weeks; pocket chambers and film badges determined the exposure of the physicians in the period studied; the team inspected the condition and operation of the equipment; and the medical officer examined the physicians for evidence of gross radiation injury.

The condition of the equipment presented shock hazards, apart from the danger of radiations. Nearly half of the machines were not grounded. Several, thought to be grounded, were not. Also, certain high voltage conductors were exposed.

Scatter or stray radiation at points where the fluoroscopist would be exposed exceeded 50 milliroentgens per minute in 14 instances. Patient's exposure to 6 of the machines exceeded 20 roentgens per minute. Another 16 were above 10 roentgens per minute. The recommended limit is 10 roentgens per minute. For infants and children, it should be much less than that.

The physicians with highest exposures were able to identify and correct errors in procedure.

By Peter J. Valaer, B.S., electronics scientist, and Mitchell R. Zavon, M.D., formerly surgeon, Occupational Health Field Headquarters, Public Health Service, Cincinnati. Dr. Zavon is now with Kettering Laboratory, Cincinnati. The full paper is to be published in the American Industrial Hygiene Association Quarterly for March 1957.

Three had worn no lead garments. One used a beam of high intensity. Another held the patient, a child, and received high dosage to his arms.

The saving factor in the situation was that more than half of the fluoroscopes were used less than 1½ minutes a week. Consequently, most exposures of physicians were well below present recommended limits.

Silicosis Prevalence Persists in Industry

PHR Silicosis persists in the United States both as an occupational hazard and as a cause of chronic if not disabling illness among many who were exposed before industrial safeguards had been established. This finding is based on a study of official records from scattered sources, described in some detail at the conference and in other publications.

The study, undertaken by the Division of Special Health Services, Bureau of State Services, Public Health Service, aimed to develop answers to four questions:

1. What is the prevalence of silicosis in the United States?
2. What are the characteristics of the silicotic population?
3. Are a significant number of new cases developing among workers entering dusty trades for the first time in the past 20 years?
4. What aspects of dust exposure need further study?

The findings of the study are to be presented in a special bulletin.

Preliminary observations indicate that the prevalence of silicosis may be several times the number of cases, more than 10,000 that were compensated or reported in one form or another in 22 States in 1950 to 1954, inclusive.

By Victoria M. Trasko, program adviser, Occupational Health Field Headquarters, Public Health Service, Cincinnati.

Geographic variations in prevalence were affected not only by industrial patterns but also by legal variations. In States where partial disability is compensable, it was to be expected that a relatively greater number of cases would be reported.

A strong indication that the number reported is below the real prevalence figure is found in the fact that in the 5-year period probably 10,000 died from occupational lung disease, but of the more than 10,000 cases reported for this study only 4 of 5 persons are known to have died.

The silicotic patients studied were in the main elderly. Of 4,814 analyzed in all stages of the disease, only 120 were under 35, 1,025 were age 35 to 49, 2,437 were 50 to 64, and 1,232 over 65. In effect, three-fourths were more than 50 years old. But in certain States, depending on the source of information, a much higher proportion of the men were relatively young. This was true especially in eastern States.

These findings provide a partial answer to the third question. Although many cases are the consequence of exposure in days when protective measures were lacking, there are enough young men who must have been exposed in recent years.

The mobility of the working force, with frequent job changes, hinders efforts of the epidem-

ologist to determine which industries are most productive of silicosis, but the highest proportion of cases appear to have been associated with mining, especially coal mining and secondarily metal mining. Of the forms of manufacture associated with silicosis, foundries appear to have been as productive of silicosis as metal mining. This analysis only suggests the most productive sources of the disease, not the relative dangers in the industries concerned.

To judge by the numbers of young men affected, no industry can be certain that it is protecting completely its employees from exposure to dust. Sufficient evidence was uncovered to suggest that either the application of dust control measures is not universal or other factors are involved. The studies suggest that, with relatively light and brief exposures to dust, the disease may take longer to develop than in the past, a possibility that cannot be determined for some years to come.

Such questions warrant further study, especially in view of the rising trend of applications for compensation or public assistance for silicotics. Future studies will be facilitated if diagnosis and reporting improve, if diagnoses and terminology are consistent, and if standards are applied to criteria of disability and to supervised employment of nondisabled silicotics.

Venereal Disease Course

The 26th Venereal Disease Postgraduate Conference for Physicians, sponsored by the University of Tennessee College of Medicine and the Public Health Service, will be held at the College of Medicine in Memphis, April 18-20, 1957.

The course is designed to acquaint the practitioner with the latest developments in diagnosis, treatment, and management of the venereal diseases. Discussion leaders for the course will be drawn from university faculties, Public Health Service personnel, and other outstanding authorities in the field.

No tuition will be charged. Applications for admission are to be sent to Dr. Henry Packer, Department of Preventive Medicine, University of Tennessee College of Medicine, Memphis 3, Tenn.

Analyzing the Tuberculosis Case Register

By HERMAN E. WIRTH, M.D., M.P.A., and BEN Z. LOCKE, M.S.

THE FIRST statewide analysis of local tuberculosis case registers in New York State, excluding New York City, was undertaken in 1952. This analysis was based on certain data contained in the registers maintained by 38 city, county, and State health district jurisdictions. The objectives were to determine the number of cases requiring supervision; to study the characteristics of known cases with respect to age, sex, residence, stage of disease, clinical status, sputum status, and type of supervision; and to evaluate the effectiveness of control activities.

The methods used and results obtained were distributed to all full-time health officers concerned and were published in detail (1). Subsequently, regional conferences were held for three major areas, Buffalo, Rochester, and Albany, for the purpose of reviewing the reported findings and of exploring methods for solving the questions raised by the analysis. These regional conferences, consisting mainly of informal roundtable discussions, were attended by regional and local health administrators, tuberculosis hospital directors, supervising public health nurses, program directors, and staff statisticians as well as representatives of local voluntary tuberculosis associations.

In 1955 a second statewide analysis was conducted from February through June to obtain similar data and to determine what changes

had occurred. The second analysis was also desirable to ascertain the indirect effects of the widespread use of antimicrobial drugs, the emergence of treatment plans on a nonhospitalized basis, and the emphasis on resectional surgery. In addition, there was the need to know what administrative steps had been taken locally to provide more and better service, streamline procedures, remove "deadwood" from the registers, and encourage possible savings. Thus, a fourth objective in the 1955 analysis was a review of the epidemiological and administrative changes in the interim period. Certain items of the 1952 analysis were discarded and other more significant ones included. At the time of the second analysis, 40 local agencies were maintaining case registers.

Administrative Aspects

The value of the case register to administrators depends on the up-to-dateness of entries relating to the persons registered. For the health officer, the register must present the significant facets of the tuberculosis problem in the community if he is to initiate in proper degree those activities needed to resolve the problem. Such activities as case and contact finding, nursing supervision, laboratory and X-ray examination, clinical consultation, treatment, hospitalization, and disposition can only be effectively conducted with the aid of timely data periodically obtained and promptly recorded in adequate detail. This need has been stressed often (2-5).

Of 23,112 cases contained in registers, 4,807 were excluded from the 1955 study because their retention in the visible case registers was not

Dr. Wirth, who has been with the New York State Department of Health since 1948, is associate director of the division of tuberculosis control. Mr. Locke, now chief of the Consultation Unit, Current Reports Section of the National Institute of Mental Health, Public Health Service, was with the New York State Department of Health from 1947 to 1956.

Geographic variations in prevalence were affected not only by industrial patterns but also by legal variations. In States where partial disability is compensable, it was to be expected that a relatively greater number of cases would be reported.

A strong indication that the number reported is below the real prevalence figure is found in the fact that in the 5-year period probably 10,000 died from occupational lung disease, but of the more than 10,000 cases reported for this study only 4 of 5 persons are known to have died.

The silicotic patients studied were in the main elderly. Of 4,814 analyzed in all stages of the disease, only 120 were under 35, 1,025 were age 35 to 49, 2,437 were 50 to 64, and 1,232 over 65. In effect, three-fourths were more than 50 years old. But in certain States, depending on the source of information, a much higher proportion of the men were relatively young. This was true especially in eastern States.

These findings provide a partial answer to the third question. Although many cases are the consequence of exposure in days when protective measures were lacking, there are enough young men who must have been exposed in recent years.

The mobility of the working force, with frequent job changes, hinders efforts of the epidem-

ologist to determine which industries are most productive of silicosis, but the highest proportion of cases appear to have been associated with mining, especially coal mining and secondarily metal mining. Of the forms of manufacture associated with silicosis, foundries appear to have been as productive of silicosis as metal mining. This analysis only suggests the most productive sources of the disease, not the relative dangers in the industries concerned.

To judge by the numbers of young men affected, no industry can be certain that it is protecting completely its employees from exposure to dust. Sufficient evidence was uncovered to suggest that either the application of dust control measures is not universal or other factors are involved. The studies suggest that, with relatively light and brief exposures to dust, the disease may take longer to develop than in the past, a possibility that cannot be determined for some years to come.

Such questions warrant further study, especially in view of the rising trend of applications for compensation or public assistance for silicotics. Future studies will be facilitated if diagnosis and reporting improve, if diagnoses and terminology are consistent, and if standards are applied to criteria of disability and to supervised employment of nondisabled silicotics.

Venereal Disease Course

The 26th Venereal Disease Postgraduate Conference for Physicians, sponsored by the University of Tennessee College of Medicine and the Public Health Service, will be held at the College of Medicine in Memphis, April 18-20, 1957.

The course is designed to acquaint the practitioner with the latest developments in diagnosis, treatment, and management of the venereal diseases. Discussion leaders for the course will be drawn from university faculties, Public Health Service personnel, and other outstanding authorities in the field.

No tuition will be charged. Applications for admission are to be sent to Dr. Henry Packer, Department of Preventive Medicine, University of Tennessee College of Medicine, Memphis 3, Tenn.

Table 3. Comparison of 1952 and 1955 percentage distributions of pulmonary tuberculosis cases, by stage of disease, New York State exclusive of New York City

| Stage of disease | 1952 | | 1955 | |
|-----------------------|---------|----------|---------|----------|
| | Number | Per-cent | Number | Per-cent |
| All stages----- | 18, 118 | 100. 0 | 16, 692 | 100. 0 |
| Minimal----- | 4, 715 | 26. 0 | 4, 068 | 24. 4 |
| Moderately advanced-- | 7, 623 | 42. 1 | 7, 190 | 43. 1 |
| Far advanced----- | 5, 059 | 27. 9 | 5, 053 | 30. 3 |
| Not stated----- | 721 | 4. 0 | 381 | 2. 3 |

by all concerned with public health" (1). The only change needed to make this statement applicable to the 1955 analysis is to note that the number of cases is now only 500 less.

The 1955 analysis reemphasized that the tuberculosis problem is greatest among men, particularly those in the older age group. Males constituted 58 percent of the registered pulmonary cases in 1952 (9) and 62 percent in 1955. The number of males registered as tuberculous remained nearly the same. The rate per 1,000 population was 2.9 for males as compared with 1.8 for females.

The 1955 prevalence rate for women reached a peak at 30 years of age, at which point it was

Figure 1. Rates for newly reported pulmonary tuberculosis cases, 1954, New York State exclusive of New York City.

only slightly higher than the rate for men. The male rate rose to a peak at 60 years. These findings are similar to those of 1952 (9). The configuration of the 1955 prevalence rates was also similar to that of the newly reported pulmonary tuberculosis case rates for 1954 (fig. 1). Of 16,692 persons with pulmonary tuberculosis, only 126 were under 15 years of age.

The 1955 review of the registers also showed that far advanced cases accounted for 34 percent of the pulmonary tuberculosis among males as compared with 25 percent for females.

The men with tuberculosis are about 10 years older than the women, and persons with minimal extent are younger than those with advanced disease (table 4).

These findings substantiate data from other sources and point up the need for continued

Table 4. Median age of pulmonary tuberculosis cases, by sex and stage of disease, 1952 and 1955, New York State exclusive of New York City

| Stage of disease | Median age in years | | | |
|-----------------------|---------------------|-------|--------|-------|
| | Male | | Female | |
| | 1952 | 1955 | 1952 | 1955 |
| All stages----- | 48. 4 | 50. 0 | 38. 2 | 39. 0 |
| Minimal----- | 45. 8 | 45. 7 | 36. 1 | 35. 6 |
| Moderately advanced-- | 49. 0 | 50. 4 | 39. 0 | 40. 1 |
| Far advanced----- | 49. 9 | 51. 4 | 38. 8 | 40. 2 |

and increased case-finding activities among men aged 45 or over.

Sputum Status

Of the 16,692 pulmonary cases on the local tuberculosis case registers in 1955, 3,166, or 19 percent, had a positive sputum in the previous 12-month period. During this same period, however, no sputum information was reported for 8,245 cases, or 50 percent (fig. 2). The percentage of cases with no sputum examinations was only slightly less than in 1952. Sputum examinations represent one of the most important items in case and contact supervision. Since facilities are available, greater

Table 1. Tuberculosis cases excluded from 1952 and 1955 analyses, New York State exclusive of New York City

| Status | 1952 | 1955 |
|--|-------|-------|
| Total..... | 4,959 | 4,807 |
| Inactive, 18 months or more..... | 3,003 | 2,927 |
| Minimal, arrested 2 years or more..... | 1,141 | 737 |
| Healed primary..... | 291 | 478 |
| Healed nonpulmonary..... | 21 | 137 |
| Suspect..... | 102 | 328 |
| Dead..... | 401 | 200 |

in accordance with the suggested criteria of the New York State Health Department (6-8). Nearly 5,000 such cases had also been excluded from the 1952 analysis (table 1). Thus, there was no significant change despite the fact that removal of the cases would have aided materially in the management of the registers.

Although the health department's criteria for removing cases from the visible registers are not mandatory, their use provides a systematic and standardized approach to related clinical and clerical management problems.

The visible case register, or active file, contains the tuberculosis case and contact register cards on all cases classified as active, arrested, and inactive for less than 18 months among residents of an area administered by a full-time local health officer. The clinical status considered here refers to the 1950 classification of pulmonary tuberculosis of the National Tuberculosis Association.

After excluding these 4,807 cases, 18,305 known tuberculosis patients were recorded as requiring active medical and nursing supervision compared with 19,923 patients in 1952. Thus, the rate per 1,000 population of 2.4 in 1955 as compared with the 2.8 in 1952 represents a decrease of only 14 percent. The rate per 1,000 population in 1955 ranged from a low of 0.8 in Allegany County to a high of 6.2 in Franklin County. In 1952 the rate varied from 0.9 for Schuyler County to 9.9 for Franklin.

In contrast, between 1951 and 1954, the years that best compare with the years in which the data on the case registers were collected, the death rate fell 53 percent and the newly reported case rate fell 26 percent. It is thus apparent that, as the emphasis on new cases is

shifted to all known cases requiring active care, the need for medical facilities, care, and supervision still definitely exists.

Prevalence

The prevalence of known tuberculosis throughout New York State, except New York City, is determined from the visible registers (active files) of the local health offices. Actually, many persons with known disease do not constitute public health hazards and consequently should be withdrawn from the active registers although they may be under the care of a clinic or private physician. Conversely, there are as yet thousands of undetected cases subject to case-finding activities.

Nevertheless, the visible registers in the local health offices provide a count of the tuberculosis cases classified as known cases significant for public health supervision.

No consequential change occurred in the percentage distribution of the various types of tuberculosis in the 3 years that had elapsed since the first analysis (table 2). Each category showed a small decrease in number, the aggregate being 1,618. As previously noted, the known prevalence rate per 1,000 population decreased from 2.8 to 2.4.

There were some minor changes in the percentage distribution by stage of disease of pulmonary cases (table 3).

When the 1952 analysis was presented it was stated, "it is apparent that, with approximately 13,000 known pulmonary cases in the moderately and far advanced stages, tuberculosis in upstate New York requires continued efforts

Table 2. Number and percent of tuberculosis cases in visible registers by type, 1952 and 1955, New York State exclusive of New York City

| Tuberculosis type | 1952 | | 1955 | |
|------------------------|---------|----------|---------|----------|
| | Num-ber | Per-cent | Num-ber | Per-cent |
| All types..... | 19,923 | 100.0 | 18,305 | 100.0 |
| Pulmonary..... | 18,118 | 90.9 | 16,692 | 91.2 |
| Other respiratory..... | 938 | 4.7 | 843 | 4.6 |
| Other forms..... | 867 | 4.4 | 770 | 4.2 |

Knowledge of the clinical status of cases is not merely of academic interest but has definite administrative value. Clinical status, in addition to the stage of disease, laboratory findings, family conditions, and so forth, determines the amount of supervision the patient and his contacts require. During 1955, 107,406 public health nursing and bedside visits were made to tuberculosis patients and contacts, representing 14.6 percent of the total visits (11). With nursing time at a premium, an up-to-date register will enable the health officer to use nursing service more effectively and economically.

Hospitalization Status

With regard to the pulmonary cases classified by clinical and hospitalization status, the findings are not too dissimilar to those of 1952 (table 6). About one-quarter were hospitalized; of the active pulmonary cases slightly

Figure 3. Sputum positive and other active pulmonary tuberculosis cases not in hospital, 1955, New York State exclusive of New York City.

Figure 4. Clinical status of pulmonary tuberculosis cases, 1955, New York State exclusive of New York City.

more than one-half were hospitalized. Of the nonhospitalized cases 25 percent were classified as active, 33 percent as arrested, 22 percent as inactive, and 20 percent not stated. Between 1952 and 1955 there was a decrease in the percentage of "active" and "activity not stated" groups. Nevertheless, the clinical status of nearly 2,500 nonhospitalized pulmonary cases was undetermined or not stated. Of these patients more than half were under chest clinic supervision and another 10 percent under the care of private physicians (fig. 5). It is recognized that there are delays in determining a patient's clinical status, but prolonged delays affect administrative decisions concerning contact examinations and nursing supervision. When such data are available and yet not entered on the visible register, the value of the register is vitiated.

Nearly 3,000 of the 12,585 nonhospitalized pulmonary cases were under no known medical supervision. About one-third of the 3,130 nonhospitalized pulmonary cases with active tuberculosis were under no known medical supervision (fig. 5). Since, by definition, a person on the register is in need of medical supervision, such unsupervised persons jeopardize their cure and rehabilitation and are potential spreaders of the disease.

Of 13,911 nonhospitalized cases of tubercu-

Figure 2. Sputum status of pulmonary tuberculosis cases, 1955, New York State exclusive of New York City.

effort to obtain sputum examinations and record the results are indicated.

Of 7,173 active or sputum positive pulmonary tuberculosis cases, less than half were hospitalized in 1955 (table 5). This is similar to the situation in 1952. Only slightly more than half of the 3,166 cases with positive sputum in the previous 12 months were hospitalized, practically no change since 1952. Is it not foolhardy to be complacent about tuberculosis while 3,740 patients who are either active or sputum positive, or both, remain unhospitalized where hos-

pital facilities are available? Of the 1,475 nonhospitalized sputum positive cases, 325 have never been hospitalized for tuberculosis. Nearly 300 of those hospitalized were treated for less than 6 months in hospitals.

As was pointed out in the 1952 analysis, "For many reasons, some more valid than others, it is difficult to hospitalize and keep hospitalized every case requiring hospitalization. Nevertheless, these reasons should be known and recorded and the number of cases in this category reduced for the welfare of the individual as well as that of the community" (10). It must be constantly remembered that these patients, even if under supervision, constitute a potential health hazard.

Nearly 1,000 active cases have no known medical supervision (fig. 3). Such cases certainly constitute a challenge in the control of tuberculosis. Systematic conference-type review of these cases by the local health officer, the clinician, and the supervising public health nurse could very well result in a significant reduction in the number of unsupervised cases.

Clinical Status

The clinical status, or activity at time of last report, of the 16,692 pulmonary cases in the active files is shown in figure 4. There were changes between 1952 and 1955, namely, a decrease in the percentage of "active" and "activity not stated" categories. Nevertheless, the clinical status of more than 3,000 cases was not stated or was undetermined.

Table 5. Sputum positive¹ and other active pulmonary cases, by hospitalization status, 1955, New York State exclusive of New York City

losis (all forms) 2,451 had not been clinically observed since 1952 (table 7). From such a large number of nonhospitalized cases, many of them active, and the large group of unsupervised cases, there arises the stark realization that much more remains to be done before

Figure 5. Clinical status and type of supervision of pulmonary tuberculosis cases not in hospital, 1955, New York State exclusive of New York City.

tuberculosis may be considered as completely controlled, much less eradicated.

Many of the patients not heard from for 12 months or more, and possibly even some with more recent cases, have undoubtedly moved away, died (without mention of tuberculosis on the death certificate), become lost, or have had inactive tuberculosis for the time period specified for transference from the administratively active file to the closed file. Some patients, despite positive sputum, may be considered as having attained maximum hospital benefit. And, of course, hospitalized patients on weekend passes with the extensive liberty to associate with such susceptible groups as young children may truly be more of a hazard than some nonhospitalized patients who are effectively isolated by geographic, economic, and social conditions.

Even so, substantial numbers of the supposedly known cases undoubtedly still have tuberculosis which has not been completely inactivated. In the light of new therapeutic approaches and surgical skills, many of them

Methemoglobinemia From Eating Meat With High Nitrite Content

By J. D. ORGERON, M.P.H., J. D. MARTIN, M.D., C. T. CARAWAY, D.V.M.,
ROSE MARY MARTINE, B.S., and GEORGE H. HAUSER, M.D.

TEN CASES of methemoglobinemia occurred near New Orleans, La., in October 1955. From epidemiological and laboratory investigations, we determined that they were due to nitrite poisoning which resulted from eating wieners and bologna containing large amounts of the chemical.

Before detailing the circumstances of the outbreak, we shall review briefly the medical aspects of methemoglobinemia and consider the use of nitrites in meat.

Methemoglobin in the Blood

Methemoglobinemia is a condition in which a part of the hemoglobin has been oxidized to methemoglobin with a consequent reduction in the oxygen-combining and oxygen-carrying power of the blood. The oxidation may be caused by absorption, inhalation, or ingestion of large doses of certain chemicals, particularly the nitrites, nitrates, sulfonamides, and aniline derivatives.

Onset of symptoms is sudden, usually within 1 or 2 hours after contact with, or ingestion of,

Mr. Orgeron, Dr. Martin, Dr. Caraway, and Miss Martine are members of the epidemiology team, Louisiana State Department of Health. Mr. Orgeron is a sanitarian epidemiologist, Dr. Martin is chief of the epidemiology section, Dr. Caraway is a veterinary epidemiologist, and Miss Martine is a nurse epidemiologist. Dr. Hauser is director of the division of laboratories and acting director of the division of food and drugs and the chemical-toxicological laboratory of the health department.

the poison. The symptoms include nausea, vomiting, profuse sweating, and an intense cyanosis of the fingertips, nose, and ears.

Mild cases of methemoglobinemia result when less than 50 percent of the hemoglobin is oxidized to methemoglobin. After 70 to 80 percent is oxidized, there is a progression of ataxia, dyspnea, excessive salivation, prostration, and unconsciousness. Oxidation of 90 percent or more is fatal unless immediate treatment is given (1).

A presumptive diagnosis of methemoglobinemia should be made if there is a history of rapid onset of cyanosis without physical findings of cardiac, pulmonary, or intracranial disorder. A history of ingestion of a substance containing nitrites or nitrates within the past few hours aids in establishing the diagnosis. If cyanosis is unrelieved by oxygen therapy and if blood withdrawn from a vein shows the characteristic chocolate-brown coloration, the diagnosis is almost certain (2).

A definitive diagnosis of methemoglobinemia can be made with the laboratory procedure reported by Evelyn and Malloy (3). This procedure, which uses a single sample of blood from the finger, is an accurate photoelectric method of determining the oxyhemoglobin, methemoglobin, and sulphemoglobin levels of the blood.

Methylene blue is an effective antidote for toxic methemoglobinemia. The recommended dosages are 1 mg. of methylene blue per kilogram of body weight for adults and 2 mg. of methylene blue per kilogram of body weight for children. These amounts should be injected

PUBLIC HEALTH SERVICE
LEROY E. BURNEY, *Surgeon General*

The remaining 8 patients exhibited symptoms similar to the first 2, and all responded well to treatment with methylene blue. Seven had eaten wieners and one had eaten bologna, all manufactured at the same plant.

Of the 10 persons ill in this outbreak, 8 were between the ages of 1½ and 5 years. For this group the interval between eating the meat and onset of symptoms was 2 hours. The other 2 patients were 10-year-olds, and the time lapse between eating the meat and onset of symptoms was about 6 hours.

Inspection of the Plant

After the report of the third case and the finding of excessive quantities of nitrite in the wieners, State and local health department sanitarians were notified to place under seizure all retail stocks of wieners manufactured by the meat plant in question. Later, when the case in which bologna appeared to be the cause was reported, some retail stocks of bologna manufactured by this plant were also seized. One or more samples from each lot of meat placed under seizure were sent to the State chemical-toxicological laboratory for nitrite determinations.

In 131 samples of the assorted meat products, nitrite concentrations varied from 3.3 p.p.m. to 6,570 p.p.m. Seventeen of the samples (14 of wieners and 3 of bologna) contained nitrites in excess of the maximum allowable of 200 p.p.m. The lots from which these samples were taken were destroyed by burning.

In an effort to determine the conditions responsible for the excessive amounts of nitrites in these meat products, we subsequently made an inspectional tour of the manufacturing plant. (This plant does not use Federal, State, or local meat inspection services.) The general manager and the sausage production manager of the plant explained each operation in the wiener and bologna manufacturing process, with particular emphasis on the mixing and blending operations.

In preparing wieners or bologna, approximately 400 pounds of coarsely ground meat and meat products are added to a silent cutter, along with ice for cooling, a prepackaged spice preparation, and 1.5 pounds of a commercially pre-

pared powder containing nitrite and nitrate. This powder is composed of approximately 6 percent sodium nitrite, 4 percent sodium nitrate, 87 percent sodium chloride, and 3 percent moisture. After 12 to 20 minutes in the silent cutter, the material is conveyed to the stuffing room, where the artificial casings are filled. Samples of the artificial casing contained only a trace of nitrite.

During our inspection of the spice storage room, we noticed an unopened container of "pure" sodium nitrate powder. On close questioning concerning the use of this powder, the sausage production manager stated that this material was just recently obtained. The commercially prepared nitrite-nitrate powder produced too fast a "cure" on some products, he explained, and he had ordered the "pure" sodium nitrate to correct this difficulty. He knew of no "pure" sodium nitrate compounds ever having been used in the plant.

Since the commercially prepared powder contained only 10 percent sodium nitrite and sodium nitrate, about 36 to 40 pounds of this material would have to be added to a 400-pound batch of meat to provide the concentration of 6,570 p.p.m. found in one sample of wieners. The amount of sodium chloride contained in 36 to 40 pounds of the commercial preparation would have made the wieners very distasteful. Hence, it would seem that a product containing a larger concentration of nitrate or nitrite (or both) than the powder would have had to be used to result in the quantities of nitrite reported by the laboratory.

After our tour of the plant, we obtained information regarding personnel changes during recent months, disposition of broken and imperfect wieners, records of nitrite and nitrate inventories, and routine laboratory controls on the meat products. Investigations of these items, however, did not help us determine how the excessive quantity of nitrite got into the wieners and bologna.

Many safeguards were taken to insure the accuracy of the chemical analyses. Two laboratories in addition to the State chemical-toxicological laboratory analyzed samples of the meat products, and all found similar nitrite concentrations. Laboratory examination of the commercially prepared powder used at the

intravenously over a 5-minute period. Dosages should not exceed 7 mg. per kilogram since toxic effects such as dyspnea, precordial pain, restlessness, a sense of oppression, apprehension, and fibrillar tremors may occur (1).

Numerous cases of methemoglobinemia have been traced to the consumption of well water containing large amounts of nitrates (4-7), contact with aniline dyes used in crayons (8-11) and laundry marking ink (12, 13), accidental ingestion of leather dyes and furniture polish (2), and ingestion or absorption of varied medications containing hemoglobin oxidizing components (14-16). Only a few outbreaks have been reported in which the causative agent was contained in food. One of these was an outbreak in New York City in which 11 aged men who had eaten breakfast at the same cafeteria were affected. Investigation showed that sodium nitrite was used in place of table salt in the seasoning of the oatmeal they had eaten (17). Another was an outbreak of acute toxic methemoglobinemia among a group of people who had eaten wheatcakes and "maple sirup" at a diner in Syracuse, N. Y. In this outbreak, investigation revealed that a commercially prepared corning extract containing 8 percent nitrites, 4 percent nitrates, and sucrose was inadvertently served as maple sirup to the affected individuals (18).

Nitrites in Meat

Nitrites and nitrates are used in curing meats mainly because of their color-fixing qualities, although these substances also have some preservative properties. When added to meat, sodium nitrate (Chile saltpeter) or potassium nitrate (saltpeter) is reduced to the corresponding nitrite by the action of certain bacteria that occur naturally in the meat and on processing equipment. The nitrites are further broken down by hydrolysis to form nitric oxide. This simple compound combines with the muscle hemoglobin (myoglobin) of the meat to form a more permanent pink substance, nitric oxide myoglobin. This pigment is more stable than the natural pigment found in blood and muscle fibers and is also more resistant to the action of air, heat, and bacteria (19).

Federal meat regulations and most of the

State food and drug regulations prohibit the use of more than 200 p.p.m. of nitrite in meat products for human consumption. These regulations also require that products containing nitrates and nitrites be labeled to that effect.

The amount of nitrite that can be utilized by meat is limited by the amount of myoglobin originally in the muscle tissues. The addition of excessive amounts of nitrites will not increase or intensify the color, but it may have an adverse effect on the meat.

Circumstances of the Outbreak

The Louisiana State Department of Health first learned of the outbreak of methemoglobinemia in the New Orleans area from a report of two cases from a practicing pediatrician.

The first patient was a 2-year-old girl who became ill about 2 hours after eating 2 wieners. Symptoms, as observed by the child's mother, included profuse sweating, vomiting, and a bluish-gray cyanosis around the lips and nails. The family physician was called immediately, and the child was hospitalized with a presumptive diagnosis of methemoglobinemia. The child responded well to an intravenous injection of methylene blue and was discharged from the hospital the following day.

Specimens of the vomitus, which contained particles of wieners, and samples of wieners obtained from the same package from which the meal was prepared were submitted to the chemical-toxicological laboratory of the State health department for determination of the nitrite content. Chemical analysis showed that the vomitus contained 11.8 p.p.m. of nitrite and that the wieners contained 5,420 p.p.m. of nitrite.

The following day the second case of methemoglobinemia was reported in a 3-year-old boy. Speech disturbance and cyanosis of the lips and nails were observed about 2 hours after the child had eaten 2 wieners manufactured by the same meat plant that prepared the ones eaten by the first patient. The child recovered rapidly after hospitalization and treatment with methylene blue injected intravenously. Samples of the wieners obtained from the same package as those eaten by this child contained 5,420 p.p.m. of nitrite.

techniques

Soda Fountain School

Employees of Cleveland's 600 drug stores will be trained at the School of Soda Fountain Sanitation operated in the city hall by the Cleveland Division of Health. Graduates will receive a food-handler's button to wear on their uniforms.

Designed to reduce the need for enforcement of sanitary regulations, the school's short course combines audience participation, group discussion, and role playing in four 2-hour sessions. Students are told and shown why a clean, colorful fountain will attract new customers, establish a regular clientele, increase sales for the drug store, and add pennies to their own pockets.

Classes began January 2, 1957. They are open to fountain employees of independent and chain stores throughout the Cleveland area in first-come, first-served order. Owner-manager representatives of the drug stores are encouraged to attend at times not used by their employees. Eventually, the course

will be offered to applicants attending high school.

The classroom seats 35. To one side is a fully equipped luncheonette, complete with mechanical dishwashing, refrigeration, and cooking facilities. All of the equipment has been donated by manufacturers and associations. Teaching aides include motion pictures, slides, flip charts, bulletin boards, pamphlets, checklists, and self-inventory sheets. Three regular and two guest instructors conduct the classes and give

everyone individual attention when needed.

On completing the course, each graduate receives a permanent number, a card, and a button. Some of the stores have agreed not to employ new help until they have earned the food-handler's button.

Every store sending all of its employees through the course receives a certificate for public display if it also has had no sanitary violations. The certificate is revokable when violations are found.

plant indicated that it did not contain more than the 10 percent sodium nitrite and sodium nitrate indicated on the label. The salt content of the wieners manufactured by the plant was found to be within normal limits.

Laboratory analysis of samples of wieners manufactured by other plants using the same commercial nitrite-nitrate preparation did not show the excessive amounts of nitrites found in the products of the plant under suspicion.

Bacteriological examination of samples of the suspected meat products did not reveal any organisms of the food-poisoning type.

Although we were unable to determine exactly how the additives were applied to the meat products to result in the excessive concentrations of nitrite, it seems most likely that a product containing a large quantity of nitrate or nitrite (or both) was mistakenly added to one or more batches of the wiener and bologna mixtures. Since the inventory controls of the additives were haphazard and the code dating of the meat products was unreliable, we were unable to learn the date that the incident occurred. Had this information been available, we could have directed our investigations to the events of the day in question.

Summary and Conclusion

In October 1955, an outbreak of 10 cases of methemoglobinemia occurred in the New Orleans, La., area. Early evidence pointed to the ingestion of large amounts of nitrite in wieners and bologna as the cause.

Investigation revealed that 9 victims had eaten wieners and 1 had eaten bologna manufactured by the same plant. Laboratory analysis of 131 samples from retail stocks of meat products manufactured by this plant indicated that 17 samples contained nitrite concentrations in excess of 200 p.p.m., the maximum amount permissible under Federal and State regulations. The concentrations ranged up to 6,570 p.p.m. A commercially prepared powder containing 10 percent sodium nitrite and sodium nitrate was used routinely in preparing the wieners and bologna.

Exactly how the excessive quantity of nitrite got into the meat products could not be determined. It seems likely, however, that a

product containing a larger quantity of nitrate or nitrite (or both) than the commercially prepared powder had been added by mistake to one or more batches of the wiener and bologna mixtures.

This outbreak demonstrates the need for effective meat inspection services in all meat packing plants. An official meat inspection program should be the aim and eventual goal of every State and municipality. In the meantime, all owners and employees of meat plants should be made aware of the dangers of careless handling of nitrates, nitrites, and other chemical additives.

• • •

Since the occurrence of this outbreak, a similar incident was reported in Florida. Two children, a 4-year-old boy and a 15-month-old girl, from the same household became ill after eating uncooked wieners. The subsequent death of the 4-year-old child has been attributed to eating the uncooked wieners.

A decline in the incidence of the venereal diseases would demonstrate effective control measures.

A reduction in the number of persons voluntarily seeking diagnosis for a venereal disease would indicate a decline in the index of suspicion on the part of the public. Such a decline might result from the conviction that venereal disease is no longer a problem.

A drop in the number of diagnosed cases reported and a reduction in direct epidemiological efforts to find suspects could result from reduced emphasis by health departments on all phases of the control programs. Reduced program content and emphasis, furthermore, may be measured by the amount or proportion of funds available to State and local health departments for venereal disease control. An analysis of the Montana central registry records demonstrated that this State's decline reflected incomplete reporting rather than true incidence. Renewed program emphasis, which included (a) the resumption of the former practice of mailing a confidential report form with all of the positive serologic reports and (b) resumption of visits to physicians to determine the diagnostic status of persons with positive serologic tests, resulted in an immediate increase in the number of reported cases.

In Montana, in July 1946, the venereal disease control program was given special em-

Table 1. Source and amount of funds budgeted for venereal disease control and number of cases of syphilis reported in Montana, fiscal years 1947-54

| Fiscal year | Funds for venereal disease control | | | Number of cases of syphilis reported |

¹ Mental health excluded.

phasis under the direction of an epidemiologist trained in venereal disease control. The growing importance of this phase of the work of State and local health units was reflected by the amount of State and local funds directed toward venereal disease control. From \$43,285 in the fiscal year 1947, funds increased to \$52,823 in 1949. Beginning in fiscal year 1950, the total amount of funds from all sources for venereal disease control declined rapidly, and by 1954 the total amount expended was only \$20,608, a decrease of 61 percent.

The number of reported cases of syphilis decreased from 291 in the fiscal year 1950 to 44 in fiscal year 1954, a decline of 84.9 percent. The amount and source of funds available for venereal disease control and the number of reported syphilis cases for fiscal years 1947-54 are shown in table 1. Table 2 shows the amount of all funds available to State and local health departments and the amount allocated to venereal disease control. The relation between the reduction in program emphasis and content as shown by the expenditure of funds and the decline in the number of syphilis cases reported is shown in figure 1.

If nothing more were known about the number of persons in Montana who had positive diagnostic tests for syphilis, it could be assumed that the State health authorities were merely exercising good judgment in reducing the amount of funds devoted to this program in about the same proportion that the disease was declining within the State. However, other data accumulated by the Montana State Board

Evidence that the content and emphasis of a syphilis control program has a greater influence over the number of cases reported than does the rise and fall in the rate of infection is adduced by one State's experience. In Montana, State board of health field work and central office efforts materially increased the number of current cases reported.

Syphilis Morbidity Reporting in Montana, 1950-54

By ARCH B. CLARK, G. D. CARLYLE THOMPSON, M.D., M.P.H., and FLORENCE KEHR, M.A.

THE MOST commonly employed measure of the incidence of syphilis within each reporting jurisdiction is the number of cases reported for the first time to State health departments. While morbidity reports comprise the principal State-by-State criterion for determining trends in the incidence of disease and evaluating public health programs, there is ample evidence that the number of cases of syphilis reported over a given period oftentimes is influenced more by the content and emphasis of the control program than by a rise or fall in the rate of infection. A classic example of this is the abrupt rise in reported cases of early latent syphilis during mobilization for World War II. The results of serologic tests for syphilis performed as part of selective service examination were directly responsible for the increased reporting of this disease.

Dramatic swings in reported morbidity such as those resulting from selective service examinations are easy to detect and interpret. It is

the subtle influence of local changes in program content and emphasis upon morbidity reporting which is difficult or impossible to detect through the routine analysis of morbidity reports. Because of the unknown factors, reported morbidity is, at best, only a crude index of trends in the control of syphilis within an individual State. Consequently, by themselves, these data may not be considered a reliable index upon which to base the program needs of a single jurisdiction.

No qualified observer will question that real progress has been made, particularly in the past 10 years, in the control of syphilis in the United States. However, just how much of the recent downward trend in reported morbidity reflects declining incidence, "under-reporting" of known cases, and case-finding failures is still a matter of speculation.

A decline in reported morbidity may result from one or more of the following factors:

1. An absolute drop in incidence or prevalence, or both.
2. A reduction in the number of infected persons seeking a diagnosis.
3. A drop in the number of diagnosed cases reported.
4. A reduction in the direct epidemiological efforts to detect suspects.

Mr. Clark is health program representative and Mrs. Kehr is records adviser with the Public Health Service, Region 8. Dr. Thompson is executive officer and secretary, Montana State Board of Health, Helena.

with cards for cases which had been reported by number or initials in 1946 or previous years. Undoubtedly there are a few Smiths and Joneses who actually were reported as cases by initials or number, 4 or more years ago, who are still receiving post-treatment serologic checks. However, since the average post-treatment observation period is probably considerably less than 3 years, the actual number of post-treatment cases taken into this study will not materially affect the overall results.

The 3,521 cases active during the period January 1, 1950–April 31, 1954, were classified as follows:

| <i>Diagnostic status</i> | <i>Number</i> | <i>Percent</i> |
|---|---------------|----------------|
| A. Diagnosed cases reported by name on State confidential morbidity report card..... | 671 | 19.1 |
| By private physician..... | 509 | |
| By clinic, hospital, or institution.. | 162 | |
| B. Cases for which central registry cards showed that a positive diagnosis of syphilis had been made but case was otherwise unreported ¹ | 440 | 12.5 |
| C. Two or more specimens examined, all tests positive..... | 523 | 14.9 |

¹ Cards for this group included those marked "control of treatment," showing that drugs had been ordered or consultation regarding treatment had been recorded, or those indicating epidemiological evidence of infection. "Epidemiological evidence of infection" involved:

(A) Central registry cards noting that the person with a positive blood test had been named as a contact of a case of primary or secondary syphilis. This was considered "epidemiological evidence" provided (a) the person was in the sexually active age group and (b) the positive blood test was subsequent to the contact report.

(B) A central registry card identified a young person with a positive test for syphilis as the child of a syphilitic mother.

The distribution of these cases by calendar year is shown in table 3.

The data in table 3 fall into three major categories of two groups each: (a) "known"

cases of syphilis, groups A and B; (b) probable cases, groups C and D; and (c) equivocal cases, groups E and F. The known cases include those for which a morbidity report has been received and those for which there is definite evidence of a diagnosis having been made. The probable cases include persons who have had one or more specimens examined for syphilis, with all tests of a battery positive and with no negative results. The equivocal cases include individuals whose serologic tests for syphilis, in addition to one or more positive reactions, resulted in one or more negative reactions. It is recognized that cases with false-positive results may be included in the probable group. On the other hand, the equivocal group, particularly group F, those with multiple STS, also must contain a significant percentage of treated but unreported cases.

It is impossible from the original data to determine the exact number of cases actually included in each of the last four categories. In order to take into consideration compensating errors in the data, when discussing morbidity reporting and case holding, the entire equivocal group has been dropped from the final analysis. It is assumed that the number of individuals with false-positive tests appearing in the "probable" group was no greater than the number of "cases" in the equivocal group. This seems to be a reasonable assumption inasmuch as the equivocal group comprises 20 percent of the total.

The total number of cases in the "known" (diagnosed) and probable categories are shown, as they occurred each year, in table 4. Also included is the number and percentage of cases within each group of these two categories. The percentage of cases in each one of these groups compared with the total cases in all groups is shown in table 5. It is evident that, had full advantage been taken of all diagnostic opportunities and had all cases been reported, some 3,050 cases of syphilis would have been reported during the 5-year period rather than 691 (table 4), a more than fourfold increase. The relationship between the cases actually reported and the potential number in the "known" group which might have been reported is shown in figure 2.

In 1950, more than 70 percent of the total

of Health demonstrate that the decline in reported morbidity of syphilis is more the result of under-reporting and case-holding failures—"suspects" who failed to remain under observation until a diagnosis had been established—than of a decrease in prevalence of this disease. Analysis of the State's morbidity reports and records of positive serologic tests for syphilis in the State laboratory demonstrates the amount of presumptive syphilis in Montana.

Central Registry

Since July 1, 1947, the Montana State Board of Health has required that all cases of syphilis be reported by name and address of the patient. Prior to this date, the regulations were satisfied by reporting cases by initials or case numbers. However, for many years it has been the practice of Montana physicians, clinics, or institutions, when sending specimens to the State laboratory for a serologic test for syphilis, to identify the donor of the specimen by full name and frequently by address and other identifying information. These two means—reporting cases by name and address and laboratory report forms which identify the person under observation by name and address—were used to prepare the "central registry" of syphilis

"cases." This file was set up in July 1947 and was prepared from lists of all known cases of syphilis previously reported by name, to which were added the names of all individuals for whom positive serologic tests had been reported. New names were added routinely from incoming morbidity and laboratory reports.

Forms provided by the State laboratory to accompany specimens sent in for serologic tests requested, in addition to the name and address of the person, the "reason for test," that is, whether "premarital," "prenatal," "diagnostic," or "control of treatment." Whenever this information was supplied, it was also entered on the central registry card.

Once a central registry card was prepared, all subsequent information pertaining to the case was recorded on that card. For example, if the first information was a positive blood test, and a morbidity report was received later from a physician, the date of the morbidity report and the identification of the reporting physician were added to the card. Other information added from time to time over the last 7 years included such items as requests from physicians for shipment of antiluetic drugs, abstracts of correspondence relating to the case, and epidemiological information. Since central registry cards are prepared for named individuals only, duplicate cards are limited to those resulting from (a) gross differences in spelling of the same name on two or more original documents, or (b) changes in surnames of women upon marriage. The first source of error is probably a minor one because supplementary information, such as a city and street address, attending physician, and clinic or institution, was checked with the central registry card for phonetically similar names. Since the caseload is heavily weighted by males, the second source of error may also be minor.

Data for this paper were obtained by an analysis of all material on file in the State board of health as of April 30, 1954. A total of 3,521 central registry cards, all of which had been active since December 31, 1949, were tabulated. Cards which were active only during the period 1947-49 were excluded in order to reduce to a minimum the error resulting from the inability to collate cards for named individuals who had positive serologic tests

Figure 1. Ratio between funds budgeted for venereal disease control in fiscal year 1949 and number of cases of syphilis reported in Montana during 1950-54.

syphilis, particularly in the past 2 years, it is apparent that many of the 1,271 persons in this group simply failed to return to the physician for results of the first test or failed to keep appointments for subsequent evaluation. It is also assumed that very few of this group received therapy for syphilis. It is reasonably certain that some of these 1,271 individuals will develop syphilitic psychoses. They will continue to populate the State mental hospitals. Others will become cardiac invalids. These are the tragedies of late untreated syphilis.

Table 5 also shows the percentage of the total known and probable cases of syphilis made up by each of the above groups. The reported cases decline from a high of 29.4 percent in 1952 to 5.9 percent in 1954. The unreported diagnosed cases do not vary significantly from the 15.7 percent average. The probable cases with two or more specimen examinations average 18.7 percent of the entire probable group. This percentage varies from 15.3 percent in 1952 to 32.4 percent in 1954. The suspected cases with a single observation comprise 41.7 percent of the probable cases. This percentage does not vary significantly throughout the entire 4½ years.

It is a matter of public concern that the State health department has no knowledge of the final diagnoses for individuals in the probable group. It may be assumed that many of the rather constant number of individuals who have had two or more specimens examined with positive results have received a definitive diag-

Figure 2. Reported cases and known cases of syphilis in Montana, 1950-54.

nosis and have been placed under treatment. However, with such strong indications of infection, it is essential for the protection of each individual that he continue under medical observation until a diagnosis is completed. Furthermore, for the protection of the public health, persons who may be in the potentially infectious stages of syphilis should be interviewed for source of infection and names of contacts.

“known” cases, had actually been reported on a State confidential report form but this proportion rapidly decreased to 22.3 percent in early 1954 (table 4). When the total number of “known” cases is taken into consideration, the decline in syphilis in Montana since 1950 is much more moderate than is indicated by the State’s morbidity reports. Comparative trends are shown in figure 3.

Case-Holding Failures

The “probable” group of syphilis cases is divided into two categories (table 4) those in-

dividuals who have two or more STS (classified as presumptive); and those who have had only a single specimen examined (classified as suspected). The number of individuals with a positive STS on a single specimen comprises approximately 70 percent of the entire probable group over the entire period. However, in 1950, 74.2 percent of the probable cases had a single specimen tested. In 1954, the percentage of probable cases having a single positive test was 62.9.

Although there has been a moderate decline in the proportion of cases in the probable group having only a single specimen tested for

physicians and hospitals in unorganized counties was delegated to a records adviser loaned to the State board of health by the Public Health Service.

Prior to the visit of State or local personnel to any area, letters from the State or local health officer were sent to all physicians to be interviewed, outlining the nature of the study and information which would be requested.

The field phases of the study began in August 1955 and, because of the vast size of the State and the limited time both State and local personnel have to devote to this work, field investigations are still continuing. By the first of January 1956, all State institutions, three of the five Indian reservations, and approximately three-fourths of the physicians and hospitals had been visited. While detailed reports on the disposition of the cases on which information was gained will not be available until the completion of the field work, the field visits and

central office activities have already had a dramatic effect upon reporting of current cases of syphilis.

For the first 6 months of 1955, the number of cases reported week by week was close to the number reported in 1954. Immediately after instituting the procedure of mailing confidential report forms with all positive laboratory reports, and following the visit of the records adviser to the first area, the number of reports of current cases of syphilis began to increase (fig. 4). By the last of October, the 43d reporting week of the year, the number of cases reported was five times that for the same period in 1954. By the end of 1955, 179 cases had been reported as compared with 31 cases in 1954, a ratio of about 6 : 1. The geographic distribution of reported cases indicates that, while there was a statewide increase in reporting, beginning with the inclusion of morbidity report cards with serologic reports, the greatest reporting gains were made in those areas visited by the records adviser.

In addition to achieving more complete reporting for syphilis, there has been a gain in the number of cases of gonorrhea and other communicable diseases reported.

Preliminary tabulations of data for 1955 would seem to substantiate the conclusions drawn from the central registry study that the major influence in the decline in number of syphilis cases reported was the result of under-reporting rather than of an absolute drop in current infections.

Summary

The number of syphilis cases reported annually in Montana has declined much more rapidly than would seem to be justified by the number of known reactors to serologic tests for syphilis.

The decline in the number of cases of syphilis reported from all sources more nearly parallels the trend in expenditures for venereal disease control by local and State health departments than it does the probable rate of infection as determined by a study of the State's central registry of reports of cases of syphilis.

During the period January 1950-April 30, 1954, 3,521 individuals with positive serologic

the State laboratory is heavily weighted by the legally required premarital and prenatal tests. This epidemiologically important group will therefore comprise the most significant portion of those persons having a single test.

Some individuals who, according to the State's record, have had a single positive STS may have a previous history of syphilis infection and will have been placed under treatment. However, those in this group who fail to remain under medical observation for sufficient time for a definite diagnosis to be made should, for their own protection and for the protection of the public, be returned to medical observation until a definitive diagnosis is established.

It is apparent that there is need not only to improve morbidity reporting in Montana but also to insure the followup and diagnosis of individuals known to have a positive serologic reaction to syphilis.

Postanalysis Activity

Upon completion of the analysis of the central registry data, plans were made, as far as limited staff and budget would permit, to utilize the information:

1. To encourage more complete day-to-day reporting.
2. To increase physicians' index of suspicion of syphilis.
3. To promote better followup of suspects.
4. To provide additional data to determine the validity of the assumptions derived from the analysis of the central office statistics and to amend the State syphilis morbidity records for each of the study years (1950-54).

These objectives were to be accomplished by staff interviews with all physicians, including medical directors of hospitals and institutions, who had submitted positive serologic specimens:

1. To procure a morbidity report attributable to the year of diagnosis for all unreported cases of syphilis.
2. To determine the number of negative cases in the study group.
3. To learn the disposition made of unresolved cases.
4. To provide a list of suspects for future followup.

The names of persons in groups B, C, and D (table 3) were listed by city of residence, each list being subdivided into those under observation for the last time in 1950-52 and those observed in 1953 or later. Information entered on the list from the central registry cards included name, date last seen, total number of serologic specimens examined, result of latest test, and group classification. Space was provided on the forms for information gained from the interviewer's visit to the physician, including diagnosis, date of diagnosis, or other disposition if no diagnosis had been made.

Responsibility for securing the information in the field was placed with the directors of the local health districts for those cases residing within their jurisdictions. Responsibility for obtaining information from State institutions, the medical services of the Indian reservations, Veterans Administration, the hospitals, and

Figure 3. Syphilis morbidity reporting in Montana, 1950-54.

Experimental Ground Water Pollution at Anchorage, Alaska

By H. J. FOURNELLE, Ph.D., E. K. DAY, M.S., and W. B. PAGE, M.S.

UNDERGROUND WATER pollution is of prime importance to public health officials concerned with safeguarding the potability of water supplies.

A study by Stiles and associates (1) has been considered a classic in this field. An extensive inquiry into ground water pollution from experimental latrines was made by Caldwell and Parr (2). And more recently the sanitary engineering research laboratory of the University of California (3, 4) has investigated several aspects relating to the conservation of ground water by the reclamation of sewage effluents through direct recharge into the ground water.

In studying the lateral movement of simulated bacterial and chemical pollutants through ground water in an Alaskan area, our first task was to find suitable indicators which would persist during a winter in a subarctic climate. These indicators were to be traced at least 1 year to determine the limits of duration or survival.

The experimental site was a small plot of land about 2 miles south of Anchorage. The

ground water table was shallow, with the top between 5 and 6 feet below the surface of the ground. Mechanical analysis of the soil at the ground water level indicated it had a sandy-gravel texture, representative of a considerable portion of the Greater Anchorage area (5).

The test agents, the dye uranin and bacteria, were introduced directly into the ground water.

The two bacterial types most commonly used for ground water pollution studies are coliform organisms and *Serratia marcescens*. But since some coliform organisms had been found sporadically in the soil of the test site, using these organisms as indicators, we felt, would cause confusion. We therefore tried, in separate tests, three chromogens in combination and an enterococcus.

In addition to the dye and bacterial tests were cultural and biochemical studies of organisms taken from the sampling wells and the dialysis of test organisms suspended in the ground water.

Tests With Dye

The dye of choice for ground water pollution studies is uranin, the sodium salt of fluorescein.

A dosing well was dug, and a galvanized pipe 10 inches in diameter was sunk into the ground water. A ring of 9 sampling wells was placed around the dosing well at a distance of approximately 3 feet. Eight- to ten-foot lengths of 1/2-inch pipe, with 12-inch wellpoints on one end and T-connections threaded onto the other, were sunk as sampling wells. The T-connections had solid metal plugs on top to facilitate pounding

Dr. Fournelle is a bacteriologist with the Epidemiology Section of the Arctic Health Research Center, Public Health Service, Anchorage, Alaska. Mr. Day was formerly chief of the Environmental Sanitation Section of the center, and Mr. Page is the present chief. Mr. Day is now with the General Engineering Program, Division of Sanitary Engineering Services, Public Health Service, Washington, D. C.

Mrs. Clarissa Allen and Mrs. Dorothea Swan gave technical laboratory assistance during several phases of the work.

tests for syphilis were under treatment or observation. Of these, 2,802 probably had syphilis. Of this "probable" group, only 23.9 percent were so reported by physicians, clinics, and institutions while 15.7 percent were known to have been treated for syphilis but were not reported as cases. An additional 18.7 percent had had two or more positive serologic tests for syphilis.

Bricks for Peru's Houses

Encouraged by the Peruvian Government's interest in housing, we have met with housing and planning officials of the newly formed Housing and Land Reform Commission and with representatives of the Inter-American Housing Center of the Pan American Union. We have been working with a local engineer on producing and marketing "sand-lime" brick in the Lima area. The project has been negotiated, and the plant, financed by Peruvian capital, is under construction.

—ELOY A. BARREDA, *sanitary engineer, United States Operations Mission, Peru.*

Water, But None to Drink

Sudden, heavy rains, over a large part of Iran, especially on the vast plains where the central desert approaches the Zarqan Mountain, badly damaged roads and other communication facilities. After road repairs permitted us to reach remote localities, we learned that the worst health problems had developed in the flat regions, some distance from the

The largest group of reactors (41.7 percent) with unknown diagnostic status had had a single test.

Field work and central office efforts by the State board of health to determine the diagnostic status of reactors, although only partially completed, have already resulted in a sixfold increase in reporting of current cases.

mountain, where flood waters had completely destroyed the villages.

Water was the most urgent need. The villagers have no natural water supply but depend on *ghanats*, underground water canals laboriously and hazardously constructed by hand, sometimes extending for many kilometers and often reaching several hundred feet in depth. The floods had filled the *ghanats* with dirt or otherwise ruined them. Water for the villages had to be carried over long distances by man and beast.

The public health department, in the emergency, dispatched 13 teams supplied with perchloron, drugs, and typhoid vaccine.

—GLEN W. McDONALD, M.D., M.P.H., *chief, Public Health Division, United States Operations Mission, Iran.*

Hospital Lottery in Iraq

In Iraq, the Mutsariff of Basrah Liwa, who recently contributed 300 dinars (\$840) toward the building of two subhealth centers, has requested a food-handlers course. Lottery funds will finance the construction of the 130-140 bed maternity hospital in Baghdad. Health films shown in the evening, twice a week, on Baghdad street corners are attracting crowds of people. The health exhibit at the agricultural fair in Sulaimaniyah was highly original: It included two mud dwellings in miniature, one sanitary and the other insanitary.

—JOHN LEWIS, M.D., *chief, Health and Sanitation Division, United States Operations Mission, Iraq.*

Figure 2. Total dye pattern, October 1951 to August 1954.

nutrient broth cultures of each of the 4 chromogens were placed in the ground water over a period of 35 days.

The water was examined for 9 weeks. It was not possible to trace the movement of these organisms. Bacteriologically, there did not appear to be any noticeable difference from the predosing examinations. A complicating factor appeared to be the large numbers of natural soil bacteria found consistently in the ground water.

It was apparent at this point that we needed some definite criteria for the selection of test organisms. These criteria were: (a) the test organism should have some specific and permanent distinguishable property, cultural or bio-

chemical, or both; (b) a laboratory test to distinguish this organism from soil bacteria should be available; and (c) the test organism should be capable of extended survival in the ground water.

Test With an Enterococcus

Certain enterococci appeared to meet the above requirements. Accordingly, a beta hemolytic, gelatin-liquefying strain, *Streptococcus zymogenes* (ATCC 4533), was obtained. (Although the culture is listed as *Streptococcus liquefaciens* in the ATCC catalog, it is designated here as *S. zymogenes* because it was beta hemolytic.) For the cultural and biochemical properties of the test organisms employed in this study, see Bergey's Manual (7).

Prior to the use of this organism, 78 samples taken from the dosing well and from 26 of the experimental test wells were examined for enterococci. Four samples were positive for non-hemolytic enterococci only.

Ten liters of 48-hour nutrient broth cultures of 2 strains of the enterococcus test organism were introduced into the ground water over a period of 11 days. A limited number of test organisms were used to see how far such a number could travel and how long they could survive.

Either 1-liter or 1-gallon samples were taken over a period of 371 days. Bacterial population was estimated by planting serial quantities of 100 ml. and less, in tenfold dilution steps, into sodium azide glucose broth (8). The remaining portion of the liter or gallon was filtered through a membrane filter (9), and the filter pad was placed in the azide glucose medium. After incubation at 45° C., positive results, as indicated by growth in the liquid medium, were confirmed by streaking a loopful of the material onto blood agar plates. The need for confirmation was pointed out by Ostrolenk and Hunter (10), who showed that false positive as well as false negative reactions occur in this medium. Microscopic examinations were made of gram-stained smears taken from the blood agar plates. Representative cultures were picked for cultural and biochemical studies.

On the third day following the initial dosing,

the pipe into the ground and $\frac{3}{4}$ -inch openings on the side for connecting a suction sampling device.

The well was dosed once with 1 liter of a 10 percent concentration of uranin to determine how long this specific amount of the dye could be detected. The method of dye concentration for ultraviolet light examination recommended by the bureau of environmental sanitation of the New York State Health Department (6) was used.

On the second day after dosing, well No. 2 in the ring (fig. 1) became positive. Five or six sampling wells were then placed in arcs at 5- to 10-foot intervals in the direction of dye movement as wells became positive for the dye.

Figure 1. Original dye pattern, October and November 1951.

There appeared to be a relatively narrow channel of dye flow, between $1\frac{1}{2}$ and 4 feet wide, with well-defined negative borders. This channel was apparent for approximately 2 to 5 weeks. The rate of movement of the dye through the ground water was about 2 feet per day.

Additional positive wells, west of the original direction of flow, were found 65 days after the original dosing. This indicates a primary and a secondary flow pattern. About 9 months after the dosing, a further shift of the dye westward was found in some of the wells. Three wells on the right border of the dye pattern had become negative.

About 2 years after the original dosing, the pattern of flow was wedge-shaped, extending from the apex at the dosing well in a northwest direction to about 40 feet in width 90 feet away. The outline of the wedge was marked by negative wells. Two years and ten months after the original dosing, dye was still evident in 38 of 48 wells examined. The dye pattern indicating all wells that were positive is shown in figure 2.

Tests With Chromogenic Bacteria

Prior to initiating the bacteriological field work, samples of the soil and ground water were examined in the laboratory for bacterial chromogens, and the effects of varying concentrations of uranin on the test organisms were compared. The first study showed that chromogens were present sporadically and in small numbers. We believed, therefore, that a group of selected bacterial chromogens together would be feasible as tracer organisms. In the second study, we found that uranin had no apparent inhibitory effect on the test organisms in concentrations that might be expected in the ground water.

The organisms used were *Serratia marcescens* (ATCC 6889), *Chromobacterium violaceum* (ATCC 553), and two strains of *Bacillus globigii* (ATCC 9372 and FDM). Cultures were obtained from the American Type Culture Collection, Washington, D. C., and the United States Army Biological Department at Fort Detrick, Md.

The dosing schedule for the bacterial chromogens was begun at the same time as the dye dosing. Nineteen 1-liter doses of 24- to 48-hour

As progress was made away from the dosing well, fewer organisms were detected. The tabulation reveals that of the positive wells in each arc, one usually had a higher concentration of the test organism. This concentration ranged from a single tenfold dilution step to 4 tenfold steps.

Ninety-five days after dosing, test organisms were detected in all positive wells except 18-10. The latter became positive during the winter when sampling was incomplete because of frozen pipes and a lowered water table. The first positive sample from this well was taken on March 8, 1954. Regression of test organisms was first noted in May, about 280 days after dosing. After 295 days, the organism was not recovered beyond 30 feet; after 316 days, not beyond 13 feet; and after 327 days, not beyond 8 feet. At the end of the study period (371 days), the only well positive for the test organism was the dosing well. The complete regression is attributed mainly to bacterial die-off and to the effect of dilution. Although Caldwell and Parr (2) considered clogging of the filtration bed an important factor in bacterial regression, we do not believe it was a primary factor in this study since a limited amount of culture material was added to the ground water.

Cultural and Biochemical Studies

Further studies were made of 282 enterococcus cultures picked from blood agar plates. On the basis of hemolysis and gelatin liquefaction, these cultures were differentiated as follows:

| Number of cultures | Beta hemolysis | Gelatin liquefaction | Identity |
|--------------------|----------------|----------------------|------------------------|
| 201 | + | + | <i>S. zymogenes</i> |
| 80 | — | — | <i>S. faecalis</i> |
| 1 | — | + | <i>S. liquefaciens</i> |

Fermentation studies detected acid production in sucrose, mannitol, sorbitol, glycerol, arabinose, and raffinose. The fermentation reactions of the *S. zymogenes* cultures were very constant. Acid was produced in 5 of the 6 sugars, the exception being raffinose. Only 1 of the 201 cultures tested varied by fermenting all 6 sugars.

The fermentation reactions of the *Streptococcus faecalis* cultures were variable and, along

with the one *S. liquefaciens* culture, differed from those of the *S. zymogenes* cultures.

Dialyzing Culture Studies

One of the factors affecting the outcome of an experimental pollution study is whether or not the test organism can survive the environmental conditions to which it is exposed. Coincidental with the tracing of the movement of the test organism through the ground water, we studied the rate and extent of die-off of 5 strains of bacteria used in two phases of the experiment. The organisms were *S. marcescens*, 2 strains of *B. globigii*, and 2 strains of *S. zymogenes*.

Nutrient broth cultures of the organisms were placed in separate dialyzing membranous sacs, made from cellophane tubing, which were then suspended in the dosing well. Exposure times varied from 24 hours to 1 year. The semi-permeable sacs retained the bacteria while permitting penetration and passage of substances in solution in the ground water into and through the membranous walls, thus simulating closely the conditions encountered by the test organisms in their travel through the ground water.

Although the rate and extent of bacterial die-off were quite pronounced for all five strains, an appreciable number of organisms survived after 1 year's exposure in the ground water. *S. marcescens* was reduced in numbers approximately 92 percent by the end of 28 days, but the surviving organisms were still well pigmented. At the end of 2 months, the decrease in numbers was 98.9 percent with some loss of pigment. After 4 months, there was no apparent further change in count, but there was a complete loss of pigmentation. Along with loss of pigment, biochemical changes, notably, a loss of fermenting powers, were also noted. The two strains of *B. globigii* showed similar losses in numbers and pigment-producing powers at the end of 28 days, and at the end of 4 months these strains were not recognizable.

The *S. zymogenes* cultures showed a progressive decrease in numbers from initial populations of 146 and 158 millions per milliliter for the two strains used to 5,800 and 4,900 per milliliter, respectively, after 1 year. Cultural and biochemical studies of isolated organisms

Figure 3. Path of test organisms, August 1953 to August 1954.

the test organism was found in the 3-foot ring of wells, and on the seventh day, in the 8-foot arc. Although this indicated a rate of movement of about 1 foot a day, it held only at those two points. The rate of flow of the test organism was irregular, averaging about 0.48 foot per day. The organism was traced to a distance of 50 feet where it was detected on the 70th day after dosing.

The test organism described a definite path of flow with sharp and clear-cut boundaries (fig. 3). The width of the path ranged between 1½ and 4 feet.

Although the organism followed a definite path, its direction did not coincide with the path of the initial dye flow observed 2 years earlier

since there had been a 26° change in the direction of the primary flow of the ground water. The path of the organism was still within the limits of the large wedge-shaped pattern formed by the dispersion of the dye. The reason for the change in direction of the ground water is not definitely known. However, there had been considerable housing construction in the area since the original dosing of the well with the dye, and the increased use of water from shallow wells may have contributed to the change in direction.

Large samples must be taken to show the test organism initially and at final sampling (see table). The bacteria gradually increased to a maximum number in most of the positive wells and then gradually decreased. This was most apparent in the wells nearest the dosing point.

Wells and samples positive for test organism

| Wells ¹ positive for test organism | Smallest amount of sample, in milliliters, showing test organism ² | | |
|---|---|--------------------------------------|----------------------------|
| | Initially | At highest concentration of organism | At final positive sampling |

¹ Wells are designated by position in feet and well No.

² Larger portions in the tenfold stepwise inoculation scheme were, in most cases, also positive while smaller portions were negative.

³ 1-liter or 1-gallon sample filtered through sterile filter paper (FP) which was placed in azide glucose medium for incubation. This test gave the only positive result.

Uranin was found to be very satisfactory for determining direction of flow of ground water. The dye was traced 100 feet from the point of dosing and was detected 2 years and 10 months later. The path of the dye varied from an initially narrow channel, 1½ to 4 feet in width, to a wedge-shaped expansion measuring 40 feet at the distal end after several years.

A member of the enterococcus group of bacteria, *Streptococcus zymogenes*, was found to be suitable as an indicator or tracer organism to determine the extent of travel through the ground water. It was possible to trace this organism for 50 feet. The width of the path of travel varied between 1½ and 4 feet.

The several bacterial chromogens used were not found suitable as test agents in this study.

The dialyzing culture study was found to be a necessary adjunct in determining the degree of survival of the test organisms in the ground water.

McGuinness Appointed Special Assistant

Dr. Aims Chamberlain McGuinness has been appointed by President Eisenhower as the new Special Assistant for Health and Medical Affairs to the Secretary of Health, Education, and Welfare. Dr. McGuinness replaces Dr. Lowell T.

Coggeshall, who resigned to resume his post as dean of the division of biological sciences at the University of Chicago.

Prior to his appointment, Dr. McGuinness practiced medicine in the field of pediatrics in Philadelphia. He has been a faculty member

at the University of Pennsylvania School of Medicine since 1934.

In the period 1948-51, Dr. McGuinness was director of the Children's Hospital in Philadelphia. He served as dean of the University of Pennsylvania Graduate School of Medicine from 1951 to 1954, and subsequently as clinical director of the Miners Memorial Hospital Association of the United Mine Workers Welfare and Retirement Fund. In this capacity, he was instrumental in constructing and staffing hospitals in the mining areas of Kentucky.

During World War II, he served as assistant administrator for the Army Epidemiological Board, and was awarded the Legion of Merit.

showed that the surviving organisms retained their original distinctive properties.

Discussion

The present study concerns methodology primarily, with emphasis on the selection of bacterial indicators. The need for such emphasis became apparent because of certain shortcomings of the several types of bacterial indicators first used in the study.

It has been shown that the enterococcus, *S. zymogenes*, is capable of long-time survival in ground water and possesses a high degree of permanency in its characteristic cultural reactions. Although there may be a pronounced reduction in numbers over a year's time, a sizable portion may be expected to survive if the initial or dosing numbers are sufficiently large.

The use of *S. marcescens* as a tracer organism has limitations because the pigmentation is a variable property. The failure of *B. globigii* may have been due to use of a mixture of vegetative cells and spores rather than a pure spore suspension.

In addition to those properties which favor the use of uranin as a chemical agent for tracing the movement of underground water, the dye was shown to have long-lasting properties in the soil and ground water, thereby facilitating prolonged studies of underground water flow. Because of the acid nature of the dye and the prevailing pH values of the ground water, it is believed that the dye could be used concurrently with the bacteria.

If dosing had been continuous, greater dye and bacterial concentrations would very likely have been found in the positive wells with possibly a resulting extension in the flow pattern of each agent.

The vertical depth to which the dye and test organisms penetrated was not determined.

The study has demonstrated that the rate and extent of die-off of bacterial test organisms in the ground water can be determined by dialyzing culture studies. The distance to which bacteria can travel through the soil via ground water is dependent upon the degree of survival of test organisms as well as the mechanical filtering action of the soil itself. The numbers of survivors will depend, in great part,

upon the numbers of bacteria introduced into the ground water. The findings of this investigation suggest the inclusion of a dialyzing culture study concurrently with the introduction of the test organism into the soil or ground water.

No doubt there are other suitable bacteria for ground water studies. Other enterococci which should also be suitable are *Streptococcus durans* and *S. liquefaciens*. *S. faecalis* is not recommended because it is considered to be the most common of the enterococci. Through the use of large samples, this organism was isolated many times.

The coliform group as a whole is not considered suitable since it is made up of a number of different species. The property of lactose fermentation by itself is not sufficiently distinctive. Because of the widespread nature of these organisms, the findings of small numbers in ground water could easily be confused with contamination from the surface of the ground. If a member of the coliform group is especially desired as a test organism, there is a possibility that *Escherichia freundii*, a coliform intermediate, might be suitable. The production of hydrogen sulfide distinguishes this organism from the other coliforms.

Some applications of the procedure given in this report are: (a) formulation of safe standards for water supplies with respect to location from points of pollution; (b) providing a method, where pollution of a water supply is suspected, of determining whether or not it has occurred or is possible; and (c) showing the availability of two highly specific simulants, a dye and a bacterium, for detection of other forms of contamination.

Summary

This study has demonstrated a method for tracing the movement of simulated chemical and bacterial pollutants in ground water. A procedure for evaluating the effects of the underground environment on the viability and on the cultural and biochemical properties of bacterial indicators is given. Emphasis is placed on the necessity of selecting as bacterial indicators, test organisms with distinctive and stable characteristics.

was last reported in 1944 and dog rabies (1 case) in 1950. Psittacosis was reported in all of these States but Missouri. Leishmaniasis was reported only in Florida and trypanosomiasis, only in Texas.

Holle states that the first two cases of American trypanosomiasis in this country were reported from Texas in 1955 (6). The etiological agent *Trypanosoma cruzi* was demonstrated in the cerebrospinal fluid of the second reported case. Six species of *Triatoma* in Texas have been found to be naturally infected with *cruzi*.

Forty-five of the forty-nine zoonoses known to occur in the south have been reported in Texas, according to a personal communication from the State epidemiologist and the Livestock Sanitary Commission. When the survey questionnaires were returned, rickettsialpox, leishmaniasis, glanders, and ratbite fever were not reported as occurring in Texas. However, Griffith and McNaughton (7) published a report of the occurrence of ratbite fever in Texas. Therefore, 46 of the 49 zoonoses actually occurred in Texas.

Foot-and-mouth disease has not occurred in the United States since 1928. Both Louisiana and Texas have recently been exposed to the threat of this disease, however, by the importation of a herd of Charolais cattle smuggled from Mexico into Louisiana through Texas. This stresses the need for constant surveillance against the importation of exotic diseases.

Q fever has been reported in Mississippi, North Carolina, Texas, Louisiana, and Virginia; rickettsialpox in Maryland, Mississippi, and Virginia.

Many wild animals are infected with, or are carriers of, infectious agents capable of causing disease in man. Fortunately, man's contact with these animals is so infrequent, or so casual, that it is only occasionally that human infections occur. It is good that this is so because many of the diseases of the lower animals are fatal to man.

Plague

Sylvatic plague occurs in at least 38 species of rodents in 14 States (8). Important species are: ground squirrels, wood rats, white-tailed prairie dogs, chipmunks, and marmots. The

disease is present among the rodents in the States on the plains east of the Rocky Mountains as well as in the States west of the Great Divide. The importance of sylvatic plague as a reservoir of human disease needs continuous investigation.

Murine plague is not an important disease in the United States at this time. The risk of infection spreading through ports and coastal cities must not be overlooked, however. A ship's docking and permitting infected rats to escape to the mainland is prevented only through constant vigilance and control.

Bubonic plague is the most common type of this infection in man—giving rise to about 75 percent of reported cases. The case fatality rate ranges from 50 to 90 percent. Epidemics in man always include a small number of cases of septicemia and secondary plague pneumonia. By aerogenic transfer these cases give rise to other cases of pneumonic plague. Pneumonic infections usually end in death. Seventeen human cases of plague have been reported in the United States since 1925 (8). Fortunately, the vectors of this disease have not had cause, except occasionally, to desert their rodent hosts for man. We must be constantly alert to the possibility of this occurrence, however.

Tularemia

Tularemia, a disease caused by a bacterium closely related to the bacillus which causes plague, has been reported in all the southern States except Alabama and Missouri. East of the Mississippi the common belief is that most cases in humans are contracted from the handling of infected rabbits. Of late, more cases associated with insect bites, particularly tick bites, have been found. Natural infection occurs in sheep and deer as well as in rodents such as ground squirrels, hares, and rabbits, and in certain wild birds, particularly quail and grouse.

Yellow Fever

Yellow fever, which ravaged Louisiana almost annually from its colonization until 1905, has not been reported in the southern States since that time. This pestilential disease is one that must be kept under constant surveillance, however, and mechanisms to prevent its

Zoonoses in the South

By J. D. MARTIN, M.D., M.P.H.

THE World Health Organization lists 87 diseases of lower animals transmissible to man (1). Of these, 49 occur in the southern United States (see table). As man's knowledge increases, still other zoonoses will probably be recognized, classified, and studied. The epidemiological concept of animal-to-man transmission is already broadening to include the concept of man to animal to man transmissibility of disease. The zoonoses, therefore, are of importance in human health and disease, and we need to know more concerning them.

Early Knowledge

Man's knowledge of some of the zoonoses dates back to antiquity, and control measures antedate recognition of the infectious nature of these diseases by hundreds of years. Although the exact cause of bacterial, rickettsial, and viral infections remained unknown to the ancients, they nevertheless developed a remarkable amount of useful information, including accurate descriptions of clinical entities and much detailed epidemiological information.

A pestilence associated with the presence of multitudes of "mice," probably bubonic plague, is mentioned in the Bible. Another disease, which could have been anthrax, is recorded in the Bible as destroying all the beasts—horses, asses, oxen, camels, and sheep—in the time of Moses.

Rabies was one of the first recognized dis-

eases. Kelser (2) says, "Plutarch asserted that, according to Athenodorus, it was observed in mankind in the days of the Aesculapidae, the descendants of Aesculapius, the god of medicine. Kelser also quotes Aristotle in the fourth century B. C. as writing that "dogs suffer from madness which puts them in a state of fury, and all animals which they bite when in this condition become also attacked with madness."

Tsutsugamushi fever, or mite typhus, is believed by Williams (3) to have been recognized as an entity since the 6th century A. D. Blake and co-workers (4) believe that it afflicted the natives of south China in the 16th century.

Epidemics of louseborne typhus probably occurred in any civilization whenever people lived under crowded, insanitary conditions. "In 1083 an epidemic occurred in Italy which, probably, was typhus. A few years later in 1106, another epidemic, apparently of the same disease, occurred in Bohemia. In both of these epidemics the outbreak followed famine" (5).

Current Status

In recent years much has been accomplished in the prevention and control of respiratory and enteric diseases. It is now time to strengthen, through adequate maintenance and surveillance programs, the gains that have been made against these diseases. It is time also to attack forcefully the zoonoses because of their increasing importance to health and economy.

During the period 1944-53, seven zoonoses—brucellosis, rabies, ringworm, salmonellosis, staphylococcosis, streptococcicosis, and tuberculosis were reported in all of the southern States and the District of Columbia. In the District of Columbia, however, human rabies (2 cases)

Dr. Martin is chief, section of epidemiology, division of preventive medicine, Louisiana State Department of Health, New Orleans, La. This is a modified version of a paper presented at the 1955 meeting of the Southern Branch of the American Public Health Association.

States since 1793. Of this number, 40,000 occurred in Louisiana where, in 1905, in the final epidemic, 900 of the 8,000 persons who developed the disease died. Yellow fever is endemic in the jungles of South and Central America, especially in the rain forests. It is also endemic in Africa (10) from the West Coast, south of the Sahara desert, through the Belgian Congo into Northern Rhodesia, Nyasaland, Uganda, Kenya, and Eritrea. The threat to America is principally through air transportation of infected individuals from endemic areas of the world into the gulf coastal United States, which has been classified as a "yellow fever receptive area" because of the large numbers of *Aedes aegypti* in this area.

South American jungle yellow fever is essentially a disease of jungle animals, especially of monkeys and marsupials. For the most part, the disease in humans is accidental, occurring when humans invade the forests. African jungle yellow fever is primarily a disease of monkeys with several species of *Aedes*, especially *Aedes africanus* and *Aedes simpsoni*, the principal vectors. Should yellow fever become established in urban areas with a high *Aedes* index, such as exists in the gulf coastal area of the United States, an epidemic could result. Only constant vigilance and control of *Aedes* can prevent this occurrence.

Typhus

Murine typhus has been fairly common in the ports and towns bordering the coast. Until the advent of widespread ectoparasite and rat eradication programs, this disease had been spreading to the cities and towns of the interior of the States bordering the coast. Studies are needed on the prevalence of this disease in rat populations. Ectoparasite and rat eradication programs should be continued.

Leptospirosis

Leptospirosis is primarily a disease of rats, dogs, sheep, goats, cattle, and swine. For many years, it has been known as an occupational disease; today it is recognized as a recreational disease as well. Most cases in humans occur in persons subjected to immersion or wetting with water containing the *Spirochaeta* or working with, or around, infected animals. Studies of

rats in Nashville (11) in 1917; in Washington, D. C. (12) prior to 1918, and in Baltimore (13) in 1924 revealed, respectively, 10, 7, and 10 percent of the rats of these cities to be infected with *Leptospira icterohaemorrhagiae*. *Leptospira pomona* infection of dairy cattle and *Leptospira canicola* infection of dogs have been demonstrated in widespread areas throughout the United States.

Arthropod-Borne Virus Diseases

Four arthropod-borne virus encephalitides occur in southern States. These are caused by closely related viruses, have birds as their natural reservoirs, and are usually spread by the bite of mosquitoes and ticks. They are eastern and western equine encephalomyelitis, St. Louis encephalitis, and louping ill or encephalomyelitis of sheep. The eastern type of equine encephalomyelitis is confined largely to the east coast of the United States from Louisiana and Florida to Massachusetts. The western type has been reported in nine southern States—Alabama, Arkansas, Florida, Louisiana, Mississippi, Missouri, Oklahoma, Tennessee, and Texas. Equine encephalomyelitis is the most important infectious disease of horses occurring in the United States at the present time.

Psittacosis

Psittacosis is annually becoming of greater importance. With increasing frequency, humans are being exposed to infection in pet psittacine birds. The disease, known as ornithosis in chickens and pigeons, will probably be diagnosed more frequently in humans as physicians become more conscious of its occurrence and diagnostic tests become more readily available. Occupational disease, resulting from employment in poultry-processing plants, particularly for turkeys, is being more often recognized. Infection may follow either fleeting or prolonged exposure.

Salmonellosis

Infected animals and birds are important sources of the increasing number of *Salmonella* infections reported in humans. There are probably hundreds of unreported and uninvestigated outbreaks of salmonellosis in the southern States each year. Rarely fatal, the

entering this country need to be perfected and maintained. Jungle yellow fever is gradually moving northward from South America. It has progressed from the jungles of northern

South America through Central America into northern Honduras.

In 1907, Carroll (9) estimated that yellow fever had caused 100,000 deaths in the United

¹ Information obtained by questionnaire sent to State departments of health and agriculture.

States since 1793. Of this number, 40,000 occurred in Louisiana where, in 1905, in the final epidemic, 900 of the 8,000 persons who developed the disease died. Yellow fever is endemic in the jungles of South and Central America, especially in the rain forests. It is also endemic in Africa (10) from the West Coast, south of the Sahara desert, through the Belgian Congo into Northern Rhodesia, Nyasaland, Uganda, Kenya, and Eritrea. The threat to America is principally through air transportation of infected individuals from endemic areas of the world into the gulf coastal United States, which has been classified as a "yellow fever receptive area" because of the large numbers of *Aedes aegypti* in this area.

South American jungle yellow fever is essentially a disease of jungle animals, especially of monkeys and marsupials. For the most part, the disease in humans is accidental, occurring when humans invade the forests. African jungle yellow fever is primarily a disease of monkeys with several species of *Aedes*, especially *Aedes africanus* and *Aedes simpsoni*, the principal vectors. Should yellow fever become established in urban areas with a high *Aedes* index, such as exists in the gulf coastal area of the United States, an epidemic could result. Only constant vigilance and control of *Aedes* can prevent this occurrence.

Typhus

Murine typhus has been fairly common in the ports and towns bordering the coast. Until the advent of widespread ectoparasite and rat eradication programs, this disease had been spreading to the cities and towns of the interior of the States bordering the coast. Studies are needed on the prevalence of this disease in rat populations. Ectoparasite and rat eradication programs should be continued.

Leptospirosis

Leptospirosis is primarily a disease of rats, dogs, sheep, goats, cattle, and swine. For many years, it has been known as an occupational disease; today it is recognized as a recreational disease as well. Most cases in humans occur in persons subjected to immersion or wetting with water containing the *Spirochaeta* or working with, or around, infected animals. Studies of

rats in Nashville (11) in 1917; in Washington, D. C. (12) prior to 1918, and in Baltimore (13) in 1924 revealed, respectively, 10, 7, and 10 percent of the rats of these cities to be infected with *Leptospira icterohaemorrhagiae*. *Leptospira pomona* infection of dairy cattle and *Leptospira canicola* infection of dogs have been demonstrated in widespread areas throughout the United States.

Arthropod-Borne Virus Diseases

Four arthropod-borne virus encephalitides occur in southern States. These are caused by closely related viruses, have birds as their natural reservoirs, and are usually spread by the bite of mosquitoes and ticks. They are eastern and western equine encephalomyelitis, St. Louis encephalitis, and louping ill or encephalomyelitis of sheep. The eastern type of equine encephalomyelitis is confined largely to the east coast of the United States from Louisiana and Florida to Massachusetts. The western type has been reported in nine southern States—Alabama, Arkansas, Florida, Louisiana, Mississippi, Missouri, Oklahoma, Tennessee, and Texas. Equine encephalomyelitis is the most important infectious disease of horses occurring in the United States at the present time.

Psittacosis

Psittacosis is annually becoming of greater importance. With increasing frequency, humans are being exposed to infection in pet psittacine birds. The disease, known as ornithosis in chickens and pigeons, will probably be diagnosed more frequently in humans as physicians become more conscious of its occurrence and diagnostic tests become more readily available. Occupational disease, resulting from employment in poultry-processing plants, particularly for turkeys, is being more often recognized. Infection may follow either fleeting or prolonged exposure.

Salmonellosis

Infected animals and birds are important sources of the increasing number of *Salmonella* infections reported in humans. There are probably hundreds of unreported and uninvestigated outbreaks of salmonellosis in the southern States each year. Rarely fatal, the

disease causes sufficient disability to account for considerable absenteeism. Over 200 salmonellae have been identified. As our knowledge of these organisms has developed, an increasing number have been found to be pathogenic to man. Poultry, swine, cattle, sheep, rodents, dogs, and other animals have been found to harbor salmonellae capable of producing disease in man.

Rabies

It is a disgrace that rabies, almost a completely preventable disease in domestic animals, is still a threat to humans. From 1946 through 1953, 42,144 cases of animal rabies were reported in the southern States (14). Of the 14 human deaths due to rabies in the United States in 1953, 13 occurred in the southern States. In the past half century more human rabies deaths have occurred in the southern States than in all of the rest of the States combined.

Bovine Mastitis

Mastitis is a major disease problem in cattle. Because of the resultant drop in milk production subsequent to the disease, it is, economically, probably the most important disease of dairy cattle. Many organisms are capable of causing bovine mastitis but streptococci and staphylococci are the most important. Usually when one animal in a herd is infected the whole herd is soon involved. To be controlled, therefore, mastitis must be attacked as a herd problem.

Brucellosis

Another major zoonosis affecting cattle and swine which places humans at risk, as well as being extremely costly, is brucellosis. Animals, apparently healthy, will show positive blood agglutination reactions during life, and at death brucellae can be isolated from the tissues of these seemingly healthy animals. Brucellosis is one of the most serious diseases with which the animal industry has to deal. Since the widespread pasteurization of milk for human consumption, brucellosis in humans is largely an occupational disease of farm people, veterinarians, and meat handlers. The economic loss resulting from its ravages runs into millions of dollars annually.

Although human brucellosis is reported each year by State health officers to the National Office of Vital Statistics, the number of reported cases is small in comparison with the number of cases that occur in animals. Few epidemiologists, therefore, attach much significance to reported figures when thinking of incidence and prevalence. Possibly a low index of suspicion of the disease by physicians and the crude diagnostic tests available for confirmation of clinical impression contribute to the small number of human cases reported.

Anthrax

In the period 1945-1951, anthrax attacked 660 herds in the southern States and caused the death of 8,311 animals. Louisiana lost more than half of this number. Only the District of Columbia and West Virginia did not report the occurrence of anthrax during this period. No disease of livestock causes greater consternation and fear than does anthrax when it makes its appearance. It strikes quickly, spreads rapidly, causes heavy losses, and, too often, is transmitted to man. Anthrax in Louisiana, Mississippi, and Texas has been recognized since 1860 or earlier (15). In 1953, Arkansas, Florida, Missouri, Oklahoma, Texas, and Virginia accounted for 50 of the 198 laboratory-confirmed outbreaks of anthrax occurring in the United States.

Louisiana has a particularly difficult problem with anthrax. The disease is endemic there, having been reported from 55 of the 64 parishes (counties). The incidence of human anthrax is relatively high also. Heeren (16) lists 111 cases as being reported from 1920-45. Since 1945, four cases have been reported.

In June, July, and August 1954, three parishes south of New Orleans—Jefferson, St. Bernard, and Plaquemines—reported a widespread outbreak of anthrax. During this same year, sporadic outbreaks were reported in eight other parishes. About 2,000 animal deaths occurred during this outbreak and 6 human cases were reported. Investigation did not confirm the diagnosis in the reported human cases.

Tuberculosis

Tuberculosis is a major public health problem because of its transmissibility to many species of

animals—a fact which persons dealing with human tuberculosis often fail to consider. Feldman says, "The organism of bovine tuberculosis is capable of infecting swine, dogs, cats, parrots, and canaries as well as human beings; the avian tubercle bacillus, besides being pathogenic for most birds, can produce destructive disease in sheep and swine, while the human type of tubercle bacillus is capable of inducing disease in cattle, swine, dogs, and parrots" (17). According to Feldman few, if any, species of animals, warm- or cold-blooded, have an absolute resistance to the disease.

The United States Department of Agriculture has had a tuberculosis eradication program for about 30 years. At the onset of the program, 5 percent of animals tested were found to be infected. During the fiscal year ending June 30, 1954, more than 10 million (10.8 percent) of the Nation's cattle were tested for tuberculosis (18). The prevalence of bovine tuberculin reactors is now down to 0.1 percent of the animals tested. Today, with bovine tuberculosis, as with human tuberculosis, mass testing gives a very low yield of cases and is extremely costly.

Louisiana is already placing increasing emphasis on good epidemiological investigation of each active case of human tuberculosis, study of suspect contacts, and the application of mass case-finding techniques on a selective basis. The livestock industry should continue its mass testing until it can develop adequate epidemiological investigation of each known reactor and diseased animal, and, in the meantime, public health agencies should give the problem careful study. There is a need to identify, locate, and destroy all reactor animals. While this is being done, it must be remembered that healthy animals can be infected with tuberculosis by infected humans. The chain man-to-animal-to-man must always be borne in mind when unexplained reactors occur in a well protected, controlled herd.

Prevalence in Humans

Except for anthrax and rabies, I have not included figures on incidence and prevalence in humans of diseases originating in animals largely because I am sure each of you is familiar

with the human problem in your own locale, and because there is grave doubt of the significance of the low number of reported cases of some of these diseases in humans in view of the widespread occurrence of these same diseases in animals. The prevalence of these diseases among so many animals with which large numbers of our population are in frequent contact emphasizes the threat to human health.

Economic Cost

The economic impact of the zoonoses is great. I do not know the cost for the southern States as separate from the United States, but the Agricultural Research Service of the United States Department of Agriculture estimates that in the period 1942-51 the average loss on livestock and poultry from diseases, parasites, and insects amounted to \$2,688 million per year. The cattle industry is rapidly expanding in the south, particularly in Louisiana, Mississippi, and Georgia. The economy of the southern States is largely agrarian. These facts, when associated with climatic conditions which favor the propagation and spread of parasitic and other diseases of animals, strongly suggest that the southern States are bearing more than their pro rata share of the annual \$2,688 million livestock and poultry loss.

Control

Obviously, the zoonoses represent a major public health threat and a serious economic loss to States which can afford neither. It is all very well to talk about the control of brucellosis in humans, for example, through the pasteurization of all milk for human consumption and through the development of laws which would insure safe, wholesome meat. Unfortunately, measures such as these only control and decrease the number of human infections; they do not prevent the disease or eliminate its cost. Our goal should be prevention through attacking and breaking the weak link in the epidemiological chain of infection while continuing to control such diseases as occur before the chain of infection is broken.

To attack this problem properly, mechanics should be developed to assure accurate, early

reporting of the occurrence of all transmissible diseases in humans and in animals; the establishment of adequate preventive and control measures; the development of a realization of the constant threat of communicable diseases; a higher index of suspicion concerning them, and the development and utilization of better diagnostic and investigational tools and methods by practitioners of medicine, both human and veterinary.

To maintain the gains made in communicable disease control in the south, all groups interested in human and animal health and in our southern economy should join together in sharing attitudes, knowledge, information, skills, methods, and plans for preventing recurrence of the great animal plagues of the past, such as rinderpest, foot-and-mouth disease, fowl pest, Texas fever (bovine piroplasmiasis), and bovine tuberculosis, and for controlling the threats of today—rabies, psittacosis, ornithosis, brucellosis, anthrax, plague, and arthropod-borne viral and rickettsial diseases—until they too can be prevented.

Summary

The transmission of diseases from animal to man and from man to animal poses a serious threat to our health and welfare. Reasonable protective, preventive, and control measures assuring a continually improving public health status and economy will develop to the extent that veterinarians, livestock owners, research workers, economists, physicians, public health officials and others coordinate their efforts and subordinate their personal desires to the development of programs of prevention and control of the zoonoses.

An experiment in Boston, Mass., suggests that a venereal disease agency can provide the generalized experience in public health required for graduate nursing students.

A Specialized Agency for Field Instruction in Public Health

By ETHEL M. EASTER, R.N., M.S., and NICHOLAS J. FIUMARA, M.D., M.P.H.

FOR YEARS nursing schools have been confronted with a shortage of facilities that can provide generalized field instruction in public health for their students. Some schools have been forced to abandon the practice of placing their students in field agencies; others, to restrict the number so placed because of quotas imposed by allocation committees. But, despite the shortage, most collegiate schools of nursing require that every student in the general nursing program complete 8 weeks of generalized field instruction in public health to qualify for the bachelor of science degree, whether the student intends to enter clinical nursing or public health nursing.

The most obvious solution to this problem is to increase the number of facilities. Philosophically, this is a sound objective, but, practically, there are many obstacles.

Since the primary function of public health agencies is to serve the public, only within the limits of their personnel and money can they

help in the education of undergraduate and graduate nurses. Voluntary agencies usually have less money and fewer personnel than they need for their immediate objectives. In addition, their decreasing caseload, which is a result of more and more patients being treated in outpatient departments instead of at home, makes for less diversity of case material. Official agencies, too, are usually hard pressed for sufficient money and personnel to perform the day-to-day activities prescribed by law.

Thus, it seems that any material increase in educational facilities must await additional funds from a population aroused to the need for such facilities. In the meantime, we must consider other possibilities for alleviating the shortage.

In Boston, Mass., we have explored the use of a specialized agency, the division of venereal diseases of the Massachusetts Department of Public Health, for generalized field instruction in public health for nurses. A specialized agency for generalized public health experience is an apparent contradiction in terms. However, our experiment suggests that a specialized agency can fulfill the requirements set down for generalized field instruction.

Events Leading to the Experiment

In the fall of 1948, the Boston College School of Nursing had a large number of graduate

Miss Easter is assistant professor of public health nursing and director of the public health nursing program, Boston College School of Nursing. She has been with the school since 1948. Dr. Fiumara is director of the division of venereal diseases, Massachusetts Department of Public Health, and lecturer in dermatology and syphilology at Tufts University Medical School and Boston University School of Medicine.

students who were planning to teach in schools of nursing after graduation. They had a broad clinical background, but they needed experience in a number of different fields of public health nursing, among them venereal disease control. Accordingly, arrangements were made with the division of venereal diseases in the Massachusetts Department of Public Health for a 1-week observation period.

The nurses were so enthusiastic about this experience that a careful study of their evaluation reports was made, followed by personal interviews. The students recommended that the period of field instruction be extended to allow them to participate actively in the division's program by doing contact interviewing and investigation. They reiterated that the 1-week observation period had been worth while for them both as nurses and as "people." Two of the nurses said that they had begun to see the venereal disease problem in a new light and felt sure that they would be better teachers for their experience.

In accordance with the requests from the students, the field instruction period was extended from 1 week to 2 weeks, and later to 4 weeks. A graduate of the Boston College School of Nursing, who majored in public health nursing, found the instruction comparable to that received in a generalized nursing agency. She recommended that the division of venereal diseases be considered as an agency for generalized public health nursing experience.

In view of the growing enrollment at the Boston College School of Nursing and the increasing difficulty of placement in the Greater Boston area, the school decided to explore the division of venereal diseases as a possible agency for an 8-week field instruction program. In the summer of 1952, Easter, a member of the school staff, worked in the division as a nurse epidemiologist, substituting for various members of the staff while they were on vacation. She was thus able to obtain firsthand information concerning the division's program, the qualifications of the supervisors and field personnel, and the type of experience a nursing student might expect to receive there.

This worker quickly became familiar with the basic pattern of the work of venereal dis-

ease nurse epidemiologists. She perceived that these specialized nurses interested themselves not only in the possible presence of venereal disease but also in its impact on the patient and his family, that they were concerned with discovering why patients became sexually promiscuous, why extramarital exposures took place, and kindred matters, and that through skillful inquiry they became familiar with other medical, social, and emotional problems in the family, some of them totally unrelated to the disease itself.

In short, the venereal disease nurse epidemiologists practiced generalized public health nursing, using the specific problem of venereal disease as their mode of approach to the family. This is not surprising when one realizes that the epidemiologist has had generalized public health training and experience before she specializes.

After 2 months' experience, the school staff member was convinced that the division of venereal diseases was a valuable source of experience in generalized public health. But would field instruction received in the division constitute the generalized educational experience required for university academic credit? This question needed careful and exact evaluation. Fortunately, criteria were available for measuring an agency's qualifications. These criteria fall into the following groups.

Qualified personnel: The students must receive field instruction under qualified public health nursing supervision in a public health agency which stresses family health. The field teachers, as well as the supervisors, must be adequately trained and qualified public health nurses.

Student experiences: The students must gain experience in family health teaching in the following areas: prenatal, postnatal, infant, preschool, school, adolescent, and adult health, geriatrics, chronic diseases, and rehabilitation.

Staff education: There must be a continuing and adequate program of staff education for the members of the public health agency.

Qualified Personnel

The division of venereal diseases, as one of the operating divisions of the Massachusetts Department of Public Health, is a State agency. It is charged by law with providing an adequate

program in the prevention and control of venereal diseases. It is also a medical care division in that it provides diagnostic and treatment services for those who have, or suspect they have, a venereal disease and are unable to afford private medical care.

The division has a statewide epidemiological service for the interviewing of patients and the followup of their contacts. Concerned with the field training program are the medical director, two public health nursing supervisors, and seven field instructors who are called nurse epidemiologists.

The director is a graduate of an approved school of medicine and the Harvard School of Public Health. He has had 6 years' experience in generalized public health as a district health officer and has specialized in the venereal diseases since 1947. He is a diplomate of the American Board of Preventive Medicine and Public Health and is a lecturer and staff member of the several medical schools and hospitals in Boston.

The two public health nursing supervisors have their certificates in public health. One has had 1 year of experience and the other 12 years with a visiting nurse association. They have had 14 and 17 years' experience, respectively, in the field of venereal diseases.

The field instructors have also had generalized training and experience before specializing. All of them have a certificate in public health nursing.

Experience in Family Health Teaching

The experience one gains from any teaching situation is a product of the interaction of a number of factors, including what the person brings into the situation from prior training and experience, the formal and informal instruction given by the agency, the facilities available, the supply of case material, the quality and quantity of supervision.

At conferences between the nursing school and division staffs, it was agreed that the minimal educational background and experience of a graduate nurse prior to her field instruction should be completion of all academic requirements of the baccalaureate curriculum for graduate nurses. As soon as the school knows what students are to be sent on field instruction,

copies of the students' educational achievement and experience are sent to the director of the division, together with the dates for their assignments.

Every graduate nursing student assigned to the division of venereal diseases receives the following instruction and experience over a period of 8 weeks:

1. Orientation on organization of the department of public health and the division of venereal diseases; the program of the division and how it is implemented; the division's relationship to other agencies. This is conducted by the medical director, the supervising public health nurses, and the senior clerical staff, on the first day of the nurse's assignment to the division and occupies 1 full day.

2. A 6-hour lecture course on the clinical and public health aspects of the venereal diseases. The clinical lectures are given by the medical director, and the public health lectures, by one of the nursing supervisors.

3. Demonstrations by the division director and by clinic physicians of active cases of gonorrhea and syphilis in State-cooperating venereal disease clinics.

4. Observation during the first 2 weeks of the principles and practices of contact interviewing and investigation. The student is assigned to observe in several districts, each district representing a different phase of the program.

5. Assignment of the student as assistant to a public health field nurse for the remaining 6 weeks. She is given cases to work up, including contacts, suspects, and lapsed cases. At first, the field nurse accompanies the student. Subsequently, 1 to 2 weeks later, the student is assigned to investigate cases by herself, but at the end of each day she reports to her field supervisor and discusses her cases with her. She also visits patients accompanied by the supervisor, who observes the following:

- Does the student establish rapport easily?
- Is the student aware of other problems the patient may have?
- What is the impact of this disease on the patient?
- What is the impact of this disease on the family?
- Are there any problems of the family which directly or indirectly contributed to the devel-

Reported venereal disease contacts and suspects in Boston, Mass., by age and marital status, 1955

opment of venereal disease or sexual promiscuity; for example, divorce, separation, desertion, maladjusted marriage, illegitimacy, unfavorable environment?

- Are there other problems in the family not related to venereal disease? These may be medical, social, economic, moral, or environmental.

- Is the patient pregnant? If so, does the student inquire about prenatal care?

- Is the student aware of other agencies, and does she refer problems to them?

- Is she an effective teacher?

The system of instruction used by the division of venereal diseases has several advantages. First, one qualified field instructor is assigned to each student. Second, the student is pre-

pared for the actual "doing" experience by didactic and observational teaching. Third, there is an adequate caseload and a sufficiently varied group of patients for the students to gain experience in the areas enumerated above: this is apparent when one examines the amount and quality of the case material.

During 1955 a total of 1,785 contacts and suspects were investigated in Boston by the division of venereal diseases. These represent the potential family case studies made by the division staff. The distribution by age groups and marital status, shown in the table, indicates that the students had an opportunity for experience in the specific areas of family health mentioned.

During 1955, 16,986 visits for venereal dis-

ease were recorded in the Boston hospitals to which the graduate nurse students were assigned during their field training. This gave the students an opportunity to gain experience in contact interviewing and also the chance to see a number of varied types of clinical cases.

We conclude that the students had adequate field supervision and that they were exposed to a sufficient number and diversity of cases to give them experience in the specific areas of family casework listed above.

Staff Education

An interested and well-informed staff is basic to the success of any program. The division of venereal diseases, therefore, has a continuing educational program designed to meet the needs of the staff. Not only are the latest fruits from research laboratories reported, but the staff participates in the division's research projects.

Each member of the nursing staff has been sent to the Alto Medical Center in Georgia for intensive postgraduate training in contact interviewing. Furthermore, staff education meetings are held regularly each month from October through June.

At the education meetings, the staff nurses have an opportunity to hear guest lecturers preeminent in their fields, many of whom are from other States. For example, during the fiscal year 1955, our out-of-state guest speakers included Dr. Evan Thomas of New York and Dr. John Cutler of Washington, D. C. The former discussed immunity in syphilis, and the latter, the results of the long-term study of untreated syphilis. Another guest speaker was Dr. Roy E. Ritts, Jr., of the Peter Bent Brigham Hospital and Harvard Medical School, who spoke on present-day antibiotics and some of the new antibiotics under research study. Dr. John L. Fromer, chief of allergy and dermatology at the Lahey Clinic, discussed allergy in syphilis, thus bringing into clinical focus the discussions of Drs. Thomas and Ritts. At one meeting, a symposium on gonorrhea was held. The guest speakers were Dr. B. G. Clark, assistant professor of urology, and Dr. George W. Mitchell, professor of gynecology, at Tufts University School of Medicine. One

spoke on gonorrhea in the male, and the other, on gonorrhea in the female.

Principles of Supervision

During her field experience, the student becomes de facto a member of the venereal disease program staff and is subject to the rules and policies of the division. However, supervision of all workers, including the students, is based on democratic principles. The impact of this approach on the student may be deduced from the excerpts of students' evaluation of their field instruction.

"The entire situation was new to me, and I believe that this experience will broaden my narrow outlook on venereal disease and its effect upon family living. Most valuable to me was to observe workers functioning in a highly democratic atmosphere. I am more convinced than ever that this is the way an organization should be administered."

"This experience should be part of the education of every graduate nurse. What impressed me most of all was the sense of individual responsibility on the part of the epidemiologists. . . . They are presumed to be mature, reliable, professional people and are treated as such at all times."

While she is with the division of venereal diseases, the student nurse participates in the staff education program and in staff conferences. Individual conferences are held with the director, the supervisory nurses, and the field instructors. With the latter, they are held daily.

Once each week, the students return to the school for seminars with other nurse students who are affiliated with other agencies. A representative of the division of venereal diseases supervisory staff is present. The seminar is conducted by the faculty members, and the students are asked to relate their experiences and bring up cases for discussion. The entire group informally discusses the cases presented from the point of view of management, errors of omission or commission, the use of existing agencies, the current thinking in that area of public health, and the achievement of the objectives of family case work. In addition, the student is asked whether her own objectives of the field

experience have been attained and whether she has been forced to change her concepts of public health either by broadening them or making a radical readjustment.

Evaluation of the Students

Evaluation of the students' work is both objective and subjective. Fortunately, in venereal disease control there are objective yardsticks which measure the efficiency of a worker. These are the various indexes, such as the contact-patient index, the ratio of contacts discovered to contacts named, the epidemiological index, and the lesion-to-lesion index. These objective evaluations are applied to the student. The subjective evaluation is based on the reports of the field and central office supervisors. Every field supervisor is required to give a personal evaluation of the student every 2 weeks. A final written report on the student is submitted at the conclusion of the field instruction by the director of the division of venereal diseases.

The last phase of the evaluation is the student's opinion of the agency and the quality of instruction received. This evaluation may be best summed up in the words of the students themselves:

"This was by far the most interesting 8 weeks I have ever spent. It made me aware of the problems involved in cleaning out venereal disease from my city. I was also fortunate in that I had an opportunity to observe what these people are doing in the way of an inservice program in order to keep abreast of things in their own field. Then the same week we were able to observe the close association between the civilians and the armed services in an attempt to keep the venereal disease rate down. It is grati-

fying to see how much is actually being done that we never hear about. I think that the epidemiologists are the most interested of all public health nurses in the education of nurses."

"This field experience was very educational and interesting. The visits to the homes in the district were by far the most valuable to me, and I now wish that the training could have been longer. I regard this as one of my very best experiences even though I do not plan on public health nursing for a career. When taking care of hospitalized patients, I will have a better understanding of the patient, particularly from such an environment and with great emotional needs."

Summary

The shortage of adequate facilities for field instruction in public health led us to investigate the use of a specialized public health agency for generalized experience. On critical examination, the division of venereal diseases of the Massachusetts Department of Public Health was found to be a suitable organization for this purpose.

This agency has adequately trained and well-qualified personnel. It provides one qualified field supervisor for each graduate nurse student, a ratio which is seldom achieved in other agencies.

An adequate supply and a diversity of cases provide full opportunity for experience in family health teaching in the areas of prenatal and postnatal care, infant, preschool, school, adolescent, and adult health, geriatrics, chronic diseases, and rehabilitation.

The division of venereal diseases has a well-organized and effective staff education program in which the nursing students participate.

Applied Epidemiology of Gonorrhea in British Columbia

By A. JOHN NELSON, M.B., Ch.B., D.P.H.

MOST HEALTH JURISDICTIONS in North America have substantially reduced morbidity from venereal disease during the past decade. British Columbia has achieved these gains since 1946, when the Province entered the postwar era with the highest rates for gonorrhea and infectious syphilis of any Canadian Province. Since that date the infectious syphilis rate has declined markedly, but the successes achieved in gonorrhea control have been much less spectacular (table 1). Hence, gonorrhea must be considered the major venereal disease problem.

No true measure of the incidence and prevalence of gonorrhea exists. Reporting is notoriously incomplete, and figures based upon morbidity reports can be used only as a partial and minimum indication of both incidence and prevalence and, at most, to evaluate trends rather than to obtain the true picture of the gonorrhea problem.

Trends in morbidity reporting of gonorrhea from 1944 through 1955 for Canada and the continental United States are shown in figure 1. In both countries, following the peak incidence of 1946, case rates declined progressively until 1951; since then, the rates have remained virtually static. These trends may be compared with those for gonorrhea morbidity re-

porting in British Columbia and adjacent Provinces over the same period (fig. 2). British Columbia participated with other Provincial health jurisdictions in the general decline in gonorrhea incidence which followed the postwar peak of 1946.

The factors contributing to this general decline in gonorrhea incidence may be analogous to those described by Moore (1) in connection with the overall decline in the incidence of syphilis. However, it appears unlikely that the immediate postwar decline in gonorrhea was attributable to the application of control measures per se, a conclusion which is borne out by the subsequent stationary or rising trend in the incidence of gonorrhea in most areas.

In British Columbia the postwar decline in gonorrhea incidence ceased as early as 1948, and gonorrhea rates were more or less stationary through 1949 and 1950 (fig. 2), whereas in Canada and the continental United States the decline in gonorrhea incidence continued until 1951. It was concluded that, if further advances were to be made in the control of gonorrhea in British Columbia, the objectives and activities of the control organization would have to be reoriented and new approaches and answers to those apparently refractory problems which were hindering our efforts would have to be devised.

Since 1949, and at an accelerated pace since 1952, a series of studies designed to shed light upon the public health problem presented by gonorrhea and upon the reasons for the relative failure of the control program has been carried on. The objectives of the studies were the elucidation of basic epidemiological information

Dr. Nelson is assistant dean and associate professor of public health, faculty of medicine, University of British Columbia, Vancouver, B. C. This paper was presented before the First International Symposium on the Venereal Diseases and Treponematoses, held in Washington, D. C., May 28-June 1, 1956.

Table 1. Number of new cases of venereal disease reported and rate per 100,000 population, British Columbia, 1944-55

| Year | Infectious syphilis | | Gonorrhea | |
|-----------|---------------------|-----------------------------|--------------|-----------------------------|
| | Number cases | Rate per 100,000 population | Number cases | Rate per 100,000 population |
| 1944----- | 380 | 40.8 | 3,358 | 360.3 |
| 1945----- | 615 | 68.0 | 3,711 | 391.0 |
| 1946----- | 834 | 83.2 | 4,618 | 460.4 |
| 1947----- | 575 | 55.1 | 4,056 | 388.6 |
| 1948----- | 239 | 22.1 | 3,608 | 333.5 |
| 1949----- | 139 | 12.5 | 3,691 | 331.6 |

regarding this infection and the development of control measures based upon applied epidemiology. The purpose of the present paper is to report upon what has been achieved to date.

Contact Tracing

Comparison of the relative advantages and disadvantages of the three major case-finding activities—education, screening of selected groups, and contact tracing—suggested that effective contact tracing offered the greatest possibilities for a focal attack upon the gonorrhea problem. By this time, the hope that penicillin therapy was so highly specific for gonococcal infection that it was sufficient to treat only known cases and that, with the onset of symptoms, contacts could be relied on to seek medical care had been disproved. Therefore, in 1949 it was decided to develop and improve contact tracing as the strategic epidemiological weapon against gonorrhea.

Prior to 1949, contact tracing had been pushed to the utmost against syphilis, which was considered to be the more serious venereal disease, whereas contact tracing against gonorrhea, although included in the case-finding program, had been haphazard and unorganized. Thus, followup of readily identifiable contacts

of gonorrhea cases reported by venereal disease clinics was pushed. Rather less effort was made to ascertain and follow up the contacts of cases reported by private physicians. Little was done to identify the reservoir of infection responsible for perpetuating the disease, and the efficiency and achievement trends of contact tracing were not quantitatively assayed.

From 1949 on, all patients seen at venereal disease clinics were interviewed for contacts. Since many gonorrhea patients were first diagnosed by private physicians, who gave inadequate or no contact information on their morbidity reports, all Provincial health units and other health agencies working in close contact with local private physicians were instructed that every gonorrhea morbidity report, "prior to submission to the division of venereal disease control, should be scrutinized for contact information. Where the attending physician fails to list a minimum of one contact per notified case, the health unit should take steps to see that he is made aware of the importance of his contribution to the overall control program. The modus operandi here should be for the health unit to make an offer of aid (in the elicitation and followup of contacts) so convincingly extended and so helpfully applied as to earn willing acceptance."

Gonorrhea contact indexes (per 100 reported cases) were maintained in order that contact tracing might be quantitated to determine its efficiency and to permit comparative evaluation

Figure 1. Number of gonorrhea cases per 100,000 population, Canada and the United States, 1944-55.

Figure 2. Number of gonorrhea cases per 100,000 population in British Columbia and in Alberta, Saskatchewan, and Manitoba, Canada, 1944-55.

of the contributions made to the program by private physicians and trained epidemiological workers from the venereal disease clinics. Critical reevaluation of the epidemiological data for 1949-53 reveals that these measures, undertaken as part of the intensive contact tracing program, were moderately successful.

Epidemiological Studies

Epidemiological studies made in 1952 and 1953 were perhaps the most important contribution to our understanding of the epidemiology of gonorrhea and were the determining factor in the introduction of selective contact tracing. These studies (2) brought out that:

1. One venereal disease patient in every three becomes a repeater.

2. There is an important sex differential in gonorrhea reporting. In 1944-52 the male to female ratio was 2.50 (table 2). This suggests the existence of a reservoir of infected and undiagnosed females and points to the necessity for increased case-finding efforts among women. In 1952, 12.7 percent of all women examined at the Vancouver Gaeol Examination Centre had untreated gonorrhea.

3. A successful epidemiological attack upon gonorrhea involves recognition of the fact that the reservoir of infection is made up of female patients, most of whom are unidentified, and that the objective of epidemiology is to bring

the infected woman to treatment before she can infect a third person. This means that the female with undiagnosed gonorrhea must be identified through her recent male contact and be brought to treatment within hours.

A focal attack upon this reservoir of gonorrhea was incorporated in a four-point "speed-zone" project instituted by the division of venereal disease control in August 1953. The objectives of this project were:

1. To interview all male gonorrhea patients for information regarding their female contacts during the 6-day period preceding onset of symptoms. It was believed that the male patient could be used as a signpost leading to an infected female contact or to a potential carrier. Efforts were concentrated upon female contacts of known infected males in the belief that infected male contacts of known infected females would come to treatment voluntarily.

2. To locate identifiable female contacts within a matter of hours in order to minimize numerical opportunities for dissemination of infection.

3. To treat female contacts immediately as suspect carriers, although, when practicable, urethral and cervical smears and cultures were to be taken before treatment. This procedure appeared justifiable because it is difficult at any time to make a bacteriological diagnosis of gonorrhea in women and even more difficult to

Table 2. New cases of gonorrhea reported, by sex, British Columbia, 1944-52

| Year | Number of cases | | | Male/female ratio |
|------------|-----------------|--------|--------|-------------------|
| | Total | Male | Female | |
| 1944----- | 3,358 | 2,460 | 898 | 2.74 |
| 1945----- | 3,711 | 2,682 | 1,029 | 2.61 |
| 1946----- | 4,618 | 3,244 | 1,374 | 2.36 |
| 1947----- | 4,056 | 2,925 | 1,131 | 2.59 |
| 1948----- | 3,608 | 2,575 | 1,033 | 2.49 |
| 1949----- | 3,694 | 2,513 | 1,181 | 2.13 |
| 1950----- | 3,627 | 2,428 | 1,199 | 2.03 |

Figure 3. Semiannual gonorrhea contact, epidemiological, and brought-to-treatment indexes, by sex, British Columbia, 1949-55.

determine that a given woman is free of infection.

4. To control community conditions facilitating the acquisition and spread of venereal disease, which was considered to be just as important in an epidemiological program of this nature as it was formerly.

Evaluation techniques were devised by developing achievement indexes, to determine whether the first two objectives were being met.

Since interviewing male patients for information regarding their significant female contacts is the crux of selective contact tracing, the contact, epidemiological, and brought-to-treatment indexes of Iskrent and Kahn (3) were used, on a semiannual sex-specific basis, for evaluation of gonorrhea contact tracing. More specifically, the sex-specific brought-to-treat-

ment index obtained from the followup of female contacts of male patients was regarded as the critical index of achievement in selective contact tracing.

Because the value of specialized contact investigation would probably be in direct proportion to the length of time by which the infectious period was shortened, followup studies were instituted to measure the elapsed time between naming of contacts and date of treatment of such contacts.

By using these techniques, the achievements of gonorrhea contact tracing during both the 5-year intensive contact-tracing period (January 1, 1949, through June 30, 1953) and the 3-year speed-zone period (July 1, 1953, through June 30, 1955) could be evaluated and contributions to the program by private physicians and

by trained epidemiological workers from the venereal disease clinics could be compared (fig. 3). In the material which follows, all achievement indexes are based upon 100 reported cases of gonorrhea in either sex. For example, the contact indexes for males measure the number of female contacts obtained by interviewing 100 male gonorrhea patients.

Although field investigation of male contacts to female gonorrhea patients was not considered worth while because of the belief that infected male contacts would come to treatment of their own accord, it was felt that useful information could be obtained by matching records. The semianual achievement indexes in the right-hand column of figure 3 indicate that most infected male contacts come to treatment voluntarily and that, as measured by the brought-to-treatment indexes, contact tracing, per se, is not and never has been a productive method of finding cases of gonorrhea in males.

A progressive and marked increase in the female contact index obtained by private physicians occurred during both the intensive contact-tracing and the speed-zone periods. Private physicians are in a position to obtain information from females regarding their male contacts. Although this information will not increase the discovery of new cases of gonorrhea in males, it may be assumed that private physicians could effect a like improvement in the male contact index by questioning male patients regarding their female contacts.

The critical indexes are those which measure the results of investigation of female contacts of male patients and should reflect both effort and achievement in reducing the reservoir of gonorrhea infection among females. The data in the left-hand column of figure 3 indicate that, over the entire period 1949-55, clinic epidemiological workers increased their contact index for males from 99 to 143. Private physicians improved their contact index from 84 to 103 during the intensive contact-tracing period but were unable to effect any further improvement and have not been able to maintain this critical index above 100 (1 female contact per reported male patient).

Similar trends are apparent in the corresponding epidemiological indexes. Clinic workers increased their epidemiological index

for males from 37 to 44 (19 percent) during the intensive contact-tracing period and, with the advent of selective contact tracing, further improved this index to a high of 69 (57 percent). The trend of the epidemiological index for private physicians followed the trend of their contact index, an early and marked increase in the epidemiological index from 19 to 33 (74 percent) during the intensive contact-tracing period being followed by a more or less stationary trend.

Results

In terms of ultimate achievement, as measured by the male brought-to-treatment indexes, during the intensive contact-tracing period the clinic epidemiologists almost doubled the number of new cases of gonorrhea discovered in females as compared with the number discovered during early 1949 and subsequently trebled this number in the speed-zone period. The pattern of the brought-to-treatment index for private physicians approximates the pattern of their contact and epidemiological indexes, with an increased yield of new cases among females during the intensive contact-tracing period followed by a period during which no further improvement was made.

Table 3. Cumulative percentage distribution of new cases of gonorrhea among females brought to treatment through contact investigation, according to time taken to bring under treatment by clinics of the division of venereal disease control, British Columbia, July 1, 1952-December 31, 1954

| Time between being named as contact and treatment (days) | Control period | | Speed-zone period | |
|--|-----------------|-----------------------|-------------------|-----------------------|
| | Number of cases | Cumulative percentage | Number of cases | Cumulative percentage |
| Less than: | | | | |
| 1----- | 10 | 3.73 | 38 | 8.30 |
| 2----- | 27 | 10.07 | 86 | 18.78 |
| 4----- | 52 | 19.40 | 140 | 30.57 |
| 8----- | 95 | 35.45 | 225 | 49.13 |
| 15----- | 145 | 54.11 | 311 | 67.91 |
| 31----- | 207 | 77.24 | 385 | 84.07 |
| 91----- | 249 | 92.91 | 418 | 93.82 |
| 365----- | 268 | 100.00 | 458 | 100.00 |

Table 4. Number of new cases of gonorrhea among females brought to treatment through contact investigation, according to time taken to bring under treatment by clinics of the division of venereal disease control, British Columbia, July 1, 1952–December 31, 1954

| Time between being named as contact and treatment (days) | Number of cases brought to treatment | | |
|--|--------------------------------------|-------------------|-------|
| | Control period | Speed zone period | Total |
| Less than 1..... | 10 | 38 | 48 |
| 1..... | 17 | 48 | 65 |
| 2-3..... | 25 | 54 | 79 |
| 4 or more..... | 216 | 318 | 531 |
| Total..... | 268 | 458 | 726 |

By means of these sex-specific contact, epidemiological, and brought-to-treatment indexes, it has been possible to analyze in some detail our data for the period 1949–55 and to demonstrate improvement in the accomplishments of contact investigation in gonorrhea control. However, there is considerable room for improvement in the contributions which might be made by both clinic epidemiologists and private physicians in particular toward the whole program.

Contact investigation in gonorrhea control is not being exploited to the utmost unless and until private physicians (*a*) are thoroughly indoctrinated with the potential importance of their contribution to contact tracing, (*b*) are made aware of the importance of the undiagnosed reservoir of gonorrhea in females, and (*c*) acquire new attitudes and skills in interviewing male gonorrhea patients for female contacts. The increasing importance of the private physician's role in gonorrhea control is also evident from the fact that whereas in 1949 private physicians submitted 36.6 percent, clinics, 60.6 percent, and other agencies, 2.8 percent of all morbidity reports, by 1955 these figures were 45.2 percent, 35.5 percent, and 19.3 percent, respectively.

It is important to locate all female contacts within a matter of hours of identification in order to minimize numerical opportunities for dissemination of infection. Therefore, it is use-

ful to know not only the contact index but also the elapsed time between the identification of the female contact and her examination and treatment. Indeed, the success or failure of the speed-zone project must be gauged by the rapidity with which infected females are brought to treatment, thus shortening the infectious period.

In order to determine whether a significantly larger number of infected female contacts were brought to treatment earlier by speed-zone techniques than by conventional contact tracing, a special study was made on clinic patients only. The numbers of new cases of gonorrhea in females brought to treatment through contact investigation during the 13 months July 1, 1952, through July 31, 1953, the latter part of the intensive contact tracing period, with the time lapse in days between identification as a contact and treatment, were compared with the numbers brought to treatment during the 17 months August 1, 1953, through December 31, 1954, the early part of the speed-zone period. The relevant data are given in tables 3 and 4.

During the speed-zone period, approximately 19 percent of all females brought to treatment were treated within 48 hours after they were named as contacts; 30 percent were treated within 4 days; and 84 percent within 1 month (table 3). The corresponding figures for the control period were 10 percent, 19 percent, and 77 percent, respectively. Statistical treatment of the data in table 4 indicates that introduction of speed-zone epidemiological techniques into the clinics of the division of venereal disease control in British Columbia was effective in significantly reducing the time between being named as a contact and treatment of female gonorrhea patients brought to treatment through contact investigation. This, in the final analysis, decreased the chances of the promiscuous male population acquiring gonorrheal infection.

how are we doing in public health?

Today, the growth and movement of population add to the complexity and multiplicity of problems of public health, with a future expectation of 200 million persons in the United States. In great unserved areas some 40 million people live, while others are not served too satisfactorily in additional geographic areas of this country. We cannot close our eyes to the impact of other changes. Close to a third of the Nation's families changed addresses in a recent 3-year period; 10 million families moved to another State; there is a tendency toward early marriage . . . thousands of women confront a prospect of 8 to 9 years of widowhood; urbanization is accompanied by a lessening of effective relationships among individuals . . . population growth has outstripped the increase in professional public health workers.

The APHA Conference Report

With the assistance and cooperation of the authors, the staff of *Public Health Reports* has summarized some 70 of the papers presented at the 81th annual meeting of the American Public Health Association and related organizations in Atlantic City.

Summaries selected for publication in the following pages are intended to present information which may not otherwise have been given adequate notice. Omitted from these selections are papers which were known to have been scheduled for early publication in the *American Journal of Public Health*; papers

whose authors provided no copies for this journal; and papers which, for one reason or another, did not seem suited to summarization.

No papers on laboratory methods are summarized here because of the understanding that they would have early publication, at least in brief form, in the *APHA Journal*.

Other papers presented at the conference are under consideration for publication in subsequent issues of *Public Health Reports*.

Names of sections and affiliated organizations which sponsored papers presented at the conference are listed below.

Sitosterol in Corn Oil, A Cholesterol Depressant

A recent experiment suggests that the presence of sitosterol in corn oil is at least in part responsible for the depressant effect of this fat on plasma cholesterol, reported Dr. J. M. R. Beveridge, in a review of his own work and that of other investigators on fat metabolism. Dr. Beveridge is at Queens University, Kingston, Ont., Canada.

His research relates to the established association between high plasma lipid levels and a high incidence of atherosclerosis. Whether or not the relationship is one of cause and effect is not yet known, Beveridge pointed out. However, he considers it justifiable, and indeed advisable, "to regard high plasma lipid concentrations as a factor that potentiates the development of atherosclerosis in humans." Diet, of all the factors that affect the concentration of cholesterol in the blood, is undoubtedly the most important, he said.

In this experiment, 52 healthy young male subjects ingested a diet high in butterfat for an initial 8-day period. Then they were divided into five groups, one of which received beta-sitosterol as a supplement. Two groups received alpha-tocopherol in differing amounts; one was transferred to a diet high in corn oil; and another was continued on the butterfat diet.

The group on the sitosterol and the one on the corn-oil diet showed a highly significant decrease in plasma cholesterol, Beveridge stated. The decrease for the former was 21.2 percent; for the latter, 23.1 percent. The alpha-tocopherol, however, had no effect, he added.

One possible reason for this unexpected result with sitosterol, he claimed, is that it was distributed uniformly throughout the formula-type ration, in contrast with the usual procedure of giving it in the

form of a suspension before, during, or just after meals.

A number of investigators had shown that beta-sitosterol brings about a cholesterol decrease in some hypercholesterolemia individuals, Beveridge remarked, but it had not been found to be effective for persons with plasma cholesterol concentrations of less than 200 mg. per 100 ml. plasma.

Animal and Vegetable Fat

Earlier experiments, according to Beveridge, demonstrated that animal fat in the diet actively raises plasma cholesterol levels and that vegetable fat (corn oil) actively lowers the levels.

In all his experiments, he used "homogeneous diets comprised of a relatively few components of definitely known composition that could be accurately made up and dispensed." This regimen, he maintained, permitted "excellent control over calorie intake and complete control over the proportion of calories derived from the main components of the diet and also regulated the mineral and vitamin intake."

The initial experiments with this regimen showed (1) that dietary cholesterol in amounts up to about 700 mg. per day had no effect on the concentration of plasma cholesterol and (2) that corn oil in the diet resulted in significantly lower plasma lipid levels than did equi-calorie amounts of butter fat.

A subsequent experiment attested to the "presence of a factor in corn oil that actively lowers plasma cholesterol levels," Beveridge stated. After a fat-free diet for 8 days, subjects were placed on a corn-oil diet for another 8 days. After the first 8 days, the plasma cholesterol level had decreased an average of 22.2 percent; after the second 8 days, it had decreased an additional 15.2 percent.

The most recent experiments have investigated the nature of the cholesterol depressant and elevating fac-

The 9 charts on the following pages are taken from recent publications issued in limited editions by the Division of Public Health Methods, Public Health Service: a chart book on health status and health manpower, issued February 1956; and a chart book on health service manpower prepared for the October 24, 1956, meeting of the National Advisory Health Council. The latter has been reissued as PHS Publication No. 511.

tors. There appear to be two factors in butterfat that tend to elevate plasma cholesterol levels, Beveridge said, one in the first fraction, presumably due to the nature of the unsaponifiable fraction or the short-chain fatty acids, and the other in all fractions.

Sees Future for Antibiotics As Food Preservative

Assets and limitations of antibiotics in preserving food were surveyed by Dr. F. E. Deatherage, professor of agricultural biochemistry, Ohio State University.

He reported that certain of the broad spectrum antibiotics have shown great potential value in delaying the spoilage of perishable fresh food, and in proper usage there appears to be no public health hazard. But he emphasized that each application must be studied individually. Not all antibiotics act the same way nor do all foods spoil the same way.

While the tetracyclines, particularly chlortetracycline, may be effective in preserving meat, penicillin is worse than nothing, for it promotes a rapid development of the normal spoilage flora, Deatherage explained. Streptomycin is of no value in preserving the high protein foods, yet it is quite effective for bacterial soft rot of certain fresh vege-

tables. All of these antibacterial agents are useless against fungal spoilage of many fruits and vegetables.

Many new and striking developments in antifungal agents are on the horizon, he said. Control of brown rot in peaches has been demonstrated. Griseofulvin and other unnamed antifungal agents show much promise in controlling phytopathogenic fungi as well as yeasts and molds which cause deterioration in many foods.

Complements Refrigeration

Antibiotics do not sterilize food, Deatherage pointed out, but, like refrigeration, they may inhibit the growth of bacteria already there. Both are most effective in controlling spoilage when the food is handled in the most sanitary manner. Neither can be used to upgrade a spoiled or inferior product. Antibiotics and refrigeration are complementary. Both can do more than either alone in controlling spoilage. But each can produce its effect without the other.

Summing up the effect of chlorotetracycline, Deatherage reported that infusion of whole or half carcasses of beef results in a keeping time of at least 72 hours, even when the internal temperature of the meat remains in the 70-85° F. range. It greatly retards slime formation and surface spoilage in the carcass, cut, or ground forms of meat, although the length of holding time depends on the temperature and original bacterial load. For ground beef originally containing 200,000 organisms per gram, 2 p.p.m. of chlorotetracycline will increase the usable life at 10° C. from 2 to as much as 9 or more days. The same holds true for pork sausage. Generally, the use of an effective antibiotic on a perishable food, such as poultry, milk, and eggs, will increase the usable life 2 to 3 times.

Although antibiotics do not offer permanent preservation, Deatherage said, their addition to refrigerated shipments in this country can reduce the waste in meat caused by tem-

perature fluctuations in transit from packer to distributor and retailer.

In countries where perishable foods are not distributed under refrigeration, antibiotics will afford a few days of keeping time for fish, milk, poultry, and meat without the high capital outlay for equipment. This would mean more meat for more people in places where animals must be brought to the point of consumption and slaughtered and eaten the same day.

Deatherage concluded that the use of antibiotics in food is a relatively new facet of an old concept: man's use of nature's biological controls for his own advantage. Control of one organism, either microscopic or macroscopic, by another through chemical means is widespread throughout nature.

Puerto Rican Health Group Improves Island's Nutrition

The Puerto Rican Nutrition Committee has done much to alleviate borderline nutritional deficiencies in Puerto Rico, said Marta Coll-Camalez, U. S. Department of Agriculture, Caribbean Area Office, San Juan, Puerto Rico.

Faulty food habits and low income are two of the main factors responsible for Puerto Rico's nutritional deficiencies, she stated. The typical diet is low in high quality protein, vitamin A, and calcium.

The committee attempts, through its education programs, and with the help and cooperation of government agencies, to improve food habits without changing the basic structure of the dietary pattern and to increase the per capita income through social and economic programs.

In the last few years, the committee's activities have made the use of enriched flour and enriched rice compulsory throughout the island. It has developed a "basic four" chart instead of the "basic seven" and has campaigned for the consumption of nonfat dry milk solids among the low-income group that cannot afford to buy whole milk.

Other educational programs include a film strip and a movie about milk and its importance in the diet and a film strip on calabaza (squash).

Campaigns are under way to fight misleading advertising concerning the nutritional value of certain products widely sold in the island, to discourage the adding of vitamin D to fresh milk, and to discourage importers of milk from using vitamin D as a selling point.

The committee is also studying diets served at government institutions. Recommendations will be made to correct deficiencies that are found.

Social Science Offers Key To Folkway Food Barriers

Collaboration between social scientists and health workers in nutrition programs was advocated by John Cassel of the School of Public Health, University of North Carolina.

Food habits are among the oldest and most deeply entrenched aspects of many cultures and cannot be easily changed or, if changed, can produce a further series of unexpected and often unwelcome reactions, Cassel said.

Before attempting to introduce innovations into an area, health workers must first know intimately and in detail the people's beliefs, attitudes, knowledge, and behavior. Second, they must determine the pattern or system into which these customs or beliefs fit.

Here, Cassel said, are contributions social scientists can make to health programs, particularly in helping determine why certain practices obtain, in predicting the difficulty in changing them, and in indicating the most helpful techniques.

Social scientists can also assist in defining subcultural groups within an area, he stated. In southern Illinois, for instance, social scientists have distinguished eight separate subcultural groups, each with their own set of attitudes toward food

and none of them based on knowledge of or interest in nutritional values. He termed concentration of the nutritionist's time on specific groups more efficient than a broad areawide program.

Zulu Food Pattern

To illustrate the relevance of social and cultural factors to health programs, Cassel related the experience over 12 years of the Polela Health Center in introducing green vegetables, eggs, and milk into the food pattern of a Zulu community in the Union of South Africa.

In 1940 the existing diet consisted mainly of a single staple, corn, a large percentage of it refined cornmeal purchased with money sent home by migrant laborers. Supplementary foods were dried beans, negligible amounts of milk, meat, and wild greens, and potatoes and pumpkins in season.

Eighty percent of the people exhibited marked stigmata of malnutrition. Pellagra and kwashiorkor were common.

The first task was the refutation of the commonly held belief of the people that this diet was the diet of their ancestors. "Had not their ancestors been strong and healthy, mighty men of valor and military deeds?"

When the health educators, all of them Bantu speaking the Zulu language, assisted groups in realizing that much of their present diet was not so traditional as they had previously maintained, the older people, with their roseate views of the "good old days," frequently led the groups in condemning the modern inferior diet.

No deep-seated symbolic values were associated with green vegetables and eggs, and their introduction mainly hinged on arduous education and demonstration. The people had enjoyed the wild greens which soil erosion had depleted. They were shown how vegetables could be cultivated in gardens. The answer to the commonly held attitude that it was uneconomical and

greedy to eat an egg which would later hatch into a chicken was improvement in the yield to provide enough eggs for both eating and breeding.

The Milk Barrier

Milk was associated with deeply rooted beliefs and customs, however, and increasing the consumption proved most difficult and complex.

Only members of the kin group of the head of a household could use milk produced by that man's cattle. His wife was excluded because she did not belong to her husband's kin group. Milk was also usually excluded from the diet of girls after puberty. During her menses or when pregnant, a woman was thought to exert an evil influence on cattle.

To these people anything that might have an evil influence on the cattle would affect the relationship between a man and his ancestors, on whose goodwill he depended for protection against misfortune and ill health.

Stressing the importance of milk as an ideal food for lactating or expectant mothers was to no avail. Analysis of the underlying beliefs indicated clearly that the barrier to greater milk consumption lay in the link between milk and the specific cattle it came from. Powdered milk was the solution. It came from cows which did not belong to any member of the tribe or any other related groups.

In addition to applying social science concepts, Cassel cautioned nutritionists against the tendency to be "culture bound." Too often, he said, food patterns which differ from the nutritionist's familiar and customary experiences are automatically labeled "bad." Attitudes and beliefs which differ from their own are regarded as illogical, misinformed, or wrong.

Current nutritional theory is based largely on animal experimentation and work with people living in a particular cultural milieu, chiefly Western culture, he pointed

out. We have little evidence to indicate that all of this theory is applicable to all people irrespective of their way of life.

Vegetable Mixes Offer Adequate Basic Diet

Vegetable mixes as the basic diet may be the most economical solution to protein malnutrition in countries with an inadequate supply of meat, according to Dr. James B. Allison of Rutgers University.

He reported that an agricultural economy designed to provide a mixture of vegetable proteins with a relatively high nutritive value is now being studied by the Institute of Nutrition of Central America and Panama, under the direction of Dr. Nevin Scrimshaw, in cooperation with agricultural agencies of member countries.

Figuring in this system is the production of enough animal products to insure good supplementation with the essential nutrients provided by milk, eggs, fish meal, and meat.

The deficient patterns of various foods, Allison explained, can be corrected in whole or in part by mutual supplementation, a corrective process that is adequate in the average mixed diet in the United States.

Addition of soybean meal to cornmeal, for example, helps correct deficiencies of the amino acids lysine and tryptophan in cornmeal. Sesame seed will improve the sulfur amino acids and increase the tryptophan further. A mixture of whole wheat and milk develops a pattern of amino acids of high nutritive value. People themselves have learned to a certain extent to supplement deficient plant food, as in suetash, he said.

Allison described the structure and functions of dietary proteins and discussed some of the newest concepts of protein synthesis. In brief, the dietary proteins supply amino acids for cellular protein synthesis and for other special metabolic purposes. Forming the pro-

tein compound are some 22 different amino acids arranged in order along a polypeptide chain.

It has been found that not all of the 22 amino acids need to be supplied by the diet although they are all required by the body, and their inclusion in the diet may relieve the body of the stresses of synthesis.

The amino acid glycine, for example, can supply the material for synthesis of all but eight in sufficient quantities to maintain nitrogen equilibrium in adult man.

The eight amino acids essential for maintenance of nitrogen equilibrium in man are isoleucine, leucine, lysine, methionine, phenylalanine, threonine, tryptophan, and valine. Possibly arginine and histidine should be added for the growth of the infant.

But in the complex story of protein synthesis the pattern of protein intake is also important. The essential amino acids must be arranged in their proper places on the protein catalyst. If any acid is missing, a break in the chain occurs and celin-

lar protein cannot be formed. A low concentration of an essential amino acid also limits synthesis.

Increased intake of a food deficient in essential amino acids, such as wheat gluten, can help correct the deficiency, but too great an increase of the deficient food may result in an excess of the other amino acids and excretion of waste nitrogen. It may also create an imbalance between nitrogen and calorie intakes, a type of imbalance commonly found in many areas of the world where low protein, high carbohydrate foods are basic to the diet.

If the dietary protein supplies the essential amino acids in a pattern appropriate for synthesis and other needs of the body, the intake can be relatively low, Allison said.

He cited the need for analyzing the dietary protein sources of the world to determine the amino acid patterns available to various peoples and for determining the ideal dietary pattern for use in evaluating these protein sources.

The present study confirmed the fact that older women are more prone to bear mongoloid children than younger women, a fact that implies that chronic, rather than acute, processes may be causative factors, Ingalls declared. Moreover, he said, a definite excess of chronic conditions, especially among the older mothers, was found in the mothers of mongoloid babies as compared with their controls.

Another finding of significance, according to the report, was that the mothers of mongoloid babies, both the younger and the older ones, had had more miscarriages or stillbirths than their controls.

On the basis of this study and others, Ingalls concluded that "mongolism has a multiple etiology from nonspecific acute and chronic stresses that are additive and active in the first trimester of pregnancy."

Indicates Way to Control Nursery Outbreaks

Since 1954, there has been a rising incidence of epidemics of staphylococcal infections among the newborn in hospital nurseries, caused by a penicillin-resistant strain of *Staphylococcus pyogenes*, according to a study conducted at the Ohio State University.

Reporting the following findings on 19 outbreaks in United States nurseries were Drs. Thomas E. Shaffer, Robert F. Sylvester, Jr., Jack N. Baldwin, and Melvin S. Rheins.

In identifying the epidemic strain, bacteriophage typing and determining the pattern of antibiotic sensitivity proved to be valuable techniques.

The principal manifestation of infection was the pustular skin lesion among infants. Breast abscesses among nursing mothers, and in some cases among the infants themselves, were observed. Fatal infections have been reported.

Nasal carriage of the virulent strain preceded clinical infection.

Maternal and Child Health . . .

Factors Causing Mongolism Differ With Maternal Age

The factors causing mongolism in the progeny of older women are quite different from the factors productive of the disease in the offspring of younger women, stated Drs. Theodore H. Ingalls, Joan G. Babbott, and F. Randolph Philbrook, Harvard University School of Public Health.

They drew this conclusion from their study of two age groups, under 34 years and 34 years or over, of mothers of mongoloid babies and controls matched for age.

Few of the younger mothers of mongoloid babies, Ingalls reported, experienced vaginal bleeding during the pregnancy (1 of 21) whereas a high percentage had retroversion of

the uterus (9 of 21). Among the controls in this age group, 4 had vaginal bleeding, but only 3 had retroversion of the uterus.

Among the older women, vaginal bleeding was much more common in mothers of mongoloid babies than in their controls (9 as compared with 1 of 31), while retroversion of the uterus was equally common in each group (9 of 31).

Speculating on the significance of these findings, Ingalls observed that "retroversion might result in a temporary compression-stagnation effect if the gravid uterus gets trapped under the sacrum at the end of the second month of pregnancy just before it is due to enlarge upward into the pelvic brim." He believes the subject deserves intensive study.

Infant Mortality

Deaths under 1 year of age per 1,000 live births, 1953

Despite the great gains that have helped infants to survive their first year, gains especially notable among nonwhites, marked differences still appear in infant mortality rates of the respective States. (PHM chart)

To control the outbreaks, it was necessary to inhibit nasal colonization. Prophylactic use of the appropriate antibiotics proved effective after ordinary measures such as isolation of those infected and hexachlorophene bathing had failed.

A disturbing feature of these epidemics was the development of infection in most cases after discharge from the hospital. The field of contagion was thus widened through contact in the home, where the organism had a persistent extensive effect. At the same time, hospital staffs were probably not immediately aware of the epidemic situation and physicians and public health personnel treating infected persons in the community had no reason to suspect the nursery as an infection source.

The most important step towards control of these epidemics is to make all staphylococcal infections in very young infants and breast abscesses in nursing mothers reportable diseases, they concluded, pointing out that local health officers would then be able to warn hospital administrators about the suspected nursery infections.

Child Loss Suggests Priority In Maternal Health Service

Fetal and neonatal deaths are concentrated among the offspring of relatively small groups of women, according to Dr. Edward R. Schlesinger and Norman C. Allaway of the New York State Department of Health.

Results of a study of single births in upstate New York in 1951 suggest a need for concentrating maternal health services in these groups of mothers, Schlesinger said. The study, the first to classify risks according to the combined factors of age of mother, number of previous children born, and number of previous children lost, showed that 18 percent of the perinatal deaths occurred in a category with 8 percent of the deliveries.

Analysis of perinatal death rates for the offspring of mothers in each

| <i>Age of mother</i> | <i>Previous children born</i> | <i>Previous children lost</i> |
|----------------------|-------------------------------|-------------------------------|
| Any age..... | 1..... | 1..... |
| Do..... | Any number..... | 2 or more..... |
| 40 and over..... | | |
| 25 and over..... | 2 or 3..... | 1..... |
| 30..... | 3 or more..... | 1 or more..... |
| 20-24..... | do..... | 0..... |
| 35 and over..... | 0..... | |

5-year age group, according to number of previous children born and number lost, showed the greatest risk of perinatal loss among the groups in the above table.

The highest perinatal mortality rates were found among women 25 years of age and older who had lost four or more previous children. Women with one previous child had the lowest perinatal mortality rate for all age groups, and the lowest rate among these mothers was among those aged 25-29.

Priority of maternal health services for those in susceptible groups should reduce perinatal mortality more than services with no system of priorities, Schlesinger concluded.

Recommends Rubella Before Pregnancy

The consequences of maternal infection from german measles (rubella) should be anticipated by immunization, in preference to coping belatedly with them by use of gamma globulin or other measures, according to Dr. Theodore H. Ingalls, Harvard University School of Public Health. The consequences of rubella are statistically negligible in children and adults, but they are large and often tragic for the embryo, he said.

Clinical observations in Australia showed that a rubella epidemic, 1939-40, left a series of pathological consequences for the unborn babies: congenital cataract, deafness, mental retardation, and heart disease. American and European reports subsequently confirmed these observations.

Although the clinical observations definitely established that rubella in the first trimester of pregnancy

frequently proves teratogenic for the fetus, the numerical risk of maternal infection was not established. To evaluate the risk, Ingalls said, the normal as well as the abnormal outcome of pregnancies complicated by rubella must be known.

Rubella cases reported in Massachusetts since 1917 indicate long-term fluctuations of spread in addition to seasonal variations. An approximate 7-year rhythm is discernible with about three of the annual cycles often approaching a peak and the next few usually receding from it. Three of the four largest outbreaks occurred during times of war.

Since inability to measure epidemiologically the impact of rubella on the embryo has been due to technical difficulties in case finding and case reporting, demonstration of teratogenicity has been limited to clinical evidence.

The challenge now, said Ingalls, is to capture the virus and dispense it in a manner similar to the vaccinia. A practical step would be to allow women who have never had rubella to become actively immunized before marriage or pregnancy, especially in times of epidemic. Although it is conceivable, he felt that an elaborate plan of immunization comparable to that against poliomyelitis seems neither necessary nor feasible. A simpler method, he suggested, would be to have the disease—naturally or artificially.

Pediatricians, physicians, and school nurses should encourage the acceptance of developing rubella naturally and the resulting immunity with the same seriousness with which they urge immunization against tetanus. With regard to artificially acquired rubella, Ingalls pointed out that until the adult population is more highly immune than at present, there is a slight risk that school children will bring the infection home to a susceptible but pregnant mother. But, there is reason to believe that the gains would quickly outdistance the losses, he concluded.

School Health . . .

New York City Evaluates School Nursing Activities

Several suggestions for freeing the nurse from clerical and other non-nursing routines were embodied in the report of a survey of public health nursing activities in school, made by the New York City Health Department. The report was presented by Grace M. McFadden and Helen A. Miller, public health nurse consultants, and Marguerite P. Chapman and Florence R. Rich, statisticians.

The school health services in New York City have expanded greatly

since 1940. Accompanying this expansion has been a decrease in the size of staff. In 1953 the bureau of public health nursing undertook to learn how nurses could use their time in school to best advantage. First, it was necessary to learn how the average nurse spends her time in school. To do this, nursing service in a sample of 115 elementary and junior high schools, both public and parochial, was studied.

The nurse spends approximately 73 percent of her time in nursing activities, 25 percent in non-nursing ones, and the remainder in such events as civil defense and fire drills. Of 21 duties broadly classified, only

13 require her professional judgment and a background of public health nursing. These range from daily inspections to 7 types of conferences, including teacher, parent, and doctor. She uses about 28 percent of her time in case-finding activities and 30 percent in followups which are included in the 13 broad classifications.

Public health assistants are a recent addition to the school health service. Under the nurses' supervision they perform clerical and semitechnical duties. The findings suggest that these public health assistants should continue to be assigned to the school, but on a regularly scheduled basis, not on an occasional basis, and at a ratio of at least 20 percent of the nurses' time.

Where this ancillary help was available, the report stated, nurses were able to increase time spent in nursing functions by 7 percent. However, nurses still continued to perform non-nursing activities when public health assistants were in the school. Obviously, clerical duties are assignable, but the survey suggested that there is need for better orientation of nurses in the ways of working with such help. Emphasis should be placed on the type of work which nurses can delegate while still maintaining overall responsibility. It also suggested a qualitative review of all nursing activities in school to determine whether more might be shared with other school personnel or assigned to ancillary help. This should lead to a more discriminating

use of nursing time for work which unquestionably should be done by nurses.

Nurse Aide Program Proves Popular

The use of nurse aides in school health clinics has the enthusiastic endorsement of Margaret A. Bauer, nursing supervisor in the Arlington County, Va., public school system.

Evolving from the need to give school nurses some assistance with record details, the Arlington program was initiated with a student aide program in one of the senior high schools in 1951 and the employment of an adult assistant in one of the high school clinics in 1952.

Since then, three other paid workers have been assigned full time to a junior or senior high school, and the student program has spread to all but two of the secondary schools.

The student program is popular with nurses, students, and parents, Bauer stated. It requires constant supervision, however, and for that reason may not be feasible under some circumstances, she added.

To qualify as an adult assistant, a person must have successfully completed high school and standard Red Cross courses in first aid and care of the sick. Past experience in working with teen-agers and active participation with the Boy Scouts and 4-H clubs plus maturity, warmth, and understanding of adolescence are desirable qualifications also.

Registered nurses are not hired as adult assistants. The adult aide is trained on the job by the professional nurse. Her general duties include first aid, administering to the ill, reporting to parents, keeping the clinic log, assisting in screening procedures, recording test data on health records, and taking charge of supplies and linens.

The Arlington program has reaped the advantages of freeing the nurse from handling approximately 30 student visits daily, of eliminating

Trend in Nursing Students

In 1955, nursing students working for a basic degree comprised 14 percent of the total number (108,000) enrolled in State-approved schools, nearly three times the percentage in 1946. Total enrollment had not increased, however. Enrollees in advanced programs had declined by nearly 50 percent since 1951. (PHM chart)

housekeeping chores from her schedule, and of keeping the clinic open in her absence. The aide is in a position to control interruptions when the nurse is talking to a parent, working with a pupil, or in conference with other members of the professional team, Bauer explained.

There are no disadvantages to the program if the aide has been selected wisely, Bauer assured. An aggressive person, she pointed out, may rebel against the constant supervision of the school nurse, and the timid soul sometimes lacks confidence.

Student aides work directly under the nurse aide. Both boys and girls are eligible. As they become trained, they carry out many of the functions of the adult assistant. The chief exception is that students are never permitted to handle confidential nursing records.

Student aides in junior high receive credit for each school year of experience. They are graded on factual knowledge and performance, and the grade is recorded on regular report cards.

Senior high students receive points toward an honor card or a school activity letter. The clinic period is arranged to coincide with study hall periods. Only boys and girls with average or better intelligence and performance are eligible. Problem students are paired with stable and mature students. Boys are never paired with boys.

The student program, Bauer noted, gives the youngsters valuable experience in the basic techniques of caring for the sick, an opportunity to assess their personal aptitudes for future vocations, and a maturing experience that will carry over into adulthood. Along with the practice of first aid, she said, they learn the rudiments of professional behavior and poise in the presence of illness and accidents.

This experience in a clinic setting has already been instrumental in recruiting future nurses from among the girls, Bauer reported. A num-

ber have formed the nucleus of a future nurses' club. Though it is not known how many have entered nursing or the allied medical professions, she knows of at least five

who have entered nursing training within the past 2 years.

"We like to think the student aide experience was a factor in choosing this profession," she said.

Dental Health . . .

Philadelphia Plans Dentistry For Homebound Patients

Provision of dental care to homebound and institutionalized patients was recommended by Dr. J. M. Wisan, chief of the section on dental health, Philadelphia Department of Public Health.

Wisan said that the Council on Dental Health of the Philadelphia County Dental Society plans to appoint a committee made up of dentists, physicians, a psychiatrist, a nurse, social workers, and other health and welfare personnel to study the dental needs of nonambulatory patients.

Suggestions have been made that this committee also train dentists to use specialized equipment and techniques for treating these patients, obtain the portable equipment necessary to treat bedbound and wheelchair patients, and formulate and implement a treatment program for them. Details of the proposed program follow.

Study of Dental Needs

In collaboration with private practitioners, we expect to assign a dentist to examine 73 homebound patients who are on the home care program of the northern division of the Albert Einstein Medical Center and 45 persons on the "meal and wheel project." This survey will provide answers to the following questions: When was dental treatment last provided? Are routine dental examinations required by this group? What types of dental treatment are required? How much

dental care is needed? How well do the patients carry out dental hygiene practices?

Professional Training

Since specialized equipment and unique techniques are needed for treating chairbound or bedbound patients, participating dentists should be taught how to treat the chronically ill. Health departments and dental schools can offer courses of training similar to those offered in the fields of oral cancer and treatment of handicapped children. Hospitals can sponsor teaching programs. Discussions of technical procedures will be necessary, and it will also be useful to study attitudes of patients and the psychological approaches required for treating chronically ill patients.

Perhaps the dental school will assign senior dental students to assist in this program so that they may obtain experience in treating homebound patients.

Equipment

Some hospital dentists have constructed ingenious devices for providing dental care for bedbound patients. For example, a dressing cart has been rebuilt into a dental bedside unit, with an attached dental engine, a spotlight, a basin, and a shelf for instruments and medicines. A portable engine and light may be used for homebound patients, and some will require a portable X-ray unit. The women's auxiliary of the dental society is raising funds for the necessary equipment. Transportation for this equipment must be arranged.

Urban-Rural Differences in Dentist Supply

Metropolitan areas in 1952 had nearly 3 times as many dentists per 100,000 population as rural areas. In all areas, about one-third of the dentists had graduated since 1935. (PHM chart)

Treatment Program

Provision for treating hospitalized, institutionalized, and homebound patients must be included in a treatment program for the chronically ill, and some hospitals have the necessary personnel and equipment to perform this task. Our plans, therefore, will be concentrated on smaller hospitals and institutions lacking dental clinics and on home treatment programs. Administrators of larger hospitals will be asked to consider the desirability and feasibility of sending dental interns and residents to homes of patients requiring treatment.

Patients

Patients unable to pay private dentists should be given priority under the program, although persons whose dentists cannot provide home treatment should be included on a fee basis. The proportion of chronically ill persons who are unable to pay for dental treatment will undoubtedly be high for two reasons: The expense of long-term illness is

crushing to most people, and the expense of providing dental treatment at home is greater than the expense of providing treatment in clinics and dental offices.

Dental Services

In well-equipped hospitals, dentists can furnish all treatment necessary for the systemic and oral health of a patient. However, in spite of the difficulties of bringing equipment into hospitals, homes, and institutions, adequate treatment should be offered patients who cannot visit the dentist. For the bedbound patient, adequate treatment would include relief of pain, removal of unsavable infected teeth, treatment and filling of carious teeth, treatment of periodontal diseases, replacement of missing teeth when necessary to maintain oral and systemic health, diagnosis and treatment of oral diseases, as well as therapeutic sedation and local and general anesthesia. When examining adults, particular attention should be given to precancerous conditions and early cancers.

Routine dental examinations at 90-day intervals for children and at 6-month intervals for adults are recommended. Because of the difficulty of treating bedbound patients, precautions that would reduce the backlog of dental defects would be advantageous. Experience indicates that regular examination and treatment do lessen the need for extensive dental care.

Pilot Program

One Philadelphia hospital plans to sponsor a pilot program of dental care for homebound and institutionalized patients, which it is hoped will lead to participation by other hospitals. Perhaps one mobile unit can be used by several hospital staffs. Staff dentists, interns, and residents may participate under the direction of their chiefs of dental service, and assignments can then be distributed so that the program will not prove burdensome for any one institution.

The health department, the Visiting Nurse Society, and other agencies interested in home medical services will be asked to help in the program. In the preliminary stages, financing will be sought from the Community Chest and from foundations. Plans for continued financing will be made later.

A register of chronically ill patients at home and in institutions is being set up by a subcommittee of the Health and Welfare Council. Hospitals have information concerning their bedbound patients, and the files of the Department of Public Assistance will be used for referrals.

Dentists interested and trained in treating bedbound chronically ill patients will be listed and assigned as needed.

Philadelphia Agencies Plan Dental Health Program

"Effective community coordination for dental health is . . . a joint action of professional groups and community agencies in developing and implementing policies and pro-

cedures for dental programs and in stimulating citizen participation to interpret policies and to attain public support through democratic processes." So stated Dr. J. M. Wisan, chief, dental health section, Philadelphia Department of Public Health, in opening the panel discussion on community planning of a dental health program.

Wisan suggested eight criteria for appraising community coordination:

1. Organization of a coordinating dental health committee by the agency sponsoring the dental program.

2. Assignment of definite responsibilities to members of the coordinating committee.

3. Designation of professional standards for the program by the dental society through its council on dental health.

4. Determination by the dental health committee of rules for accepting patients, types of locations of clinics, standards of treatment, measures to provide an adequate flow of patients, and dental health education measures.

5. Organization of local, district, and neighborhood committees to stimulate citizen participation in large cities.

6. Agreement of administrators of community dental care programs on a plan of reporting regularly to the coordinating committee: number of persons receiving treatment, number of visits by patients, number of teeth filled and type of fillings, numbers of permanent and deciduous teeth extracted, number of other treatments provided, fees charged per visit or per operation, rules for eligibility of patients, and number of dentist-hours spent in treatment.

7. Participation by the coordinating committee in evaluation and re-direction of the dental program.

8. Invitations by the dental health committee to key persons in the community to help organize and attend conferences for discussion and improvement of existing dental programs.

Other participants in the discussions were Drs. Abraham Cohen, supervisor of dental services, Board of Public Education; John P. Loohey, dental supervisor, Philadelphia parochial schools; Albert L. Borish, chairman, Council on Dental Health, Philadelphia County Dental Society; and J. L. T. Appleton, professor of microbiology, University of Pennsylvania School of Dentistry.

Public Schools

An incremental dental care program for public school children has been carried on by the Philadelphia Department of Health since 1954, Cohen reported. In the beginning, treatment was restricted to 6-year-olds, although some teen-agers were treated when time permitted, and emergencies were handled. This year, he said, the accumulated needs of 8-year-olds and the maintenance needs of the 6- and 7-year-olds treated during the past 2 years will be taken care of.

Dental clinics are being established in school buildings, Cohen said, minimum standards of treatment have been compiled, and spot checking of completed dental work is carried on in school districts. School nurses are responsible for the flow of patients to the dental clinics. Nurses bring eligible pupils to the clinic or arrange for a parent to bring them. Nurses also see that clinic time is used to treat older children if the number of 6- and 7-year-olds is insufficient.

The board of education has endeavored to eliminate the sale of sweets by private vendors in school cafeterias and school yards and to encourage the pupils to eat fresh fruit instead. Fruits purchased by school principals through wholesalers are delivered to the school. Visual aids are used to promote the program.

This project, plus Philadelphia's fluoridated water supply, "will do more to increase the percentage of caries-free teeth than any other aspect of dental health education," Cohen stated.

Parochial Schools

In Philadelphia's parochial schools, a program of periodic dental examinations, sponsored by the State health department, was begun in 1946, Loohey stated, and from the beginning the program has been integrated with the county dental society's council on dental health.

Projects to promote dental health in the parochial schools have included an annual poster contest, assembly programs and distribution of educational materials, sale of toothbrushes at a reduced rate, membership in the coordinating committee of the Philadelphia County Dental Society, cooperation of the nursing corps of the schools in the selection of children for clinic treatment, installation of dental clinics in 5 schools and 1 settlement house, establishment of an escort service for the children, and coordination of efforts to obtain dental care in three hospitals.

The key group in coordinating the efforts of all agencies has been the council on dental health of the Philadelphia County Dental Society, Loohey said, and membership in that group has made possible expansion of a program which provides the best care for parochial school pupils within the framework of organized dentistry.

County Dental Society

Reporting on the work of the Philadelphia County Dental Society's Council on Dental Health, Borish said that the council's efforts had resulted in "a true community approach to community dental health problems." The council, he stated, has six objectives:

1. To have all agencies with dental programs represented on the council, with voting privileges.

2. To have all policies approved by the board of governors of the county society.

3. To be the informational center for community dental needs and resources.

4. To help coordinate all community dental programs so that they will perform the maximum service.

5. To help each agency obtain community support.

6. To help evaluate programs and induce improvements.

The revised Standards for Dental Procedures for the Child has been sent to all public and private dental agencies in Philadelphia, Borish stated, and has been published in local and State journals.

The subcommittee on dental agency administrators has made plans to standardize programs and records, he said, and refresher courses have been offered by and for hospital staff dentists.

Finally, through work conferences, community groups have come to recognize the objectives of the dental health program and are cooperating in achieving them, Borish concluded.

Health and Welfare Council

Concerning the role played by the Health and Welfare Council in promoting community dental health, Appleton stated that one of the council's most important functions is "to encourage, and to participate in, the processes of effective coordination."

The council has sponsored or co-sponsored dental surveys, studies, and conferences and is reviewing the resources available or required to meet dental health needs in Philadelphia.

Reviewing the panel discussions, Appleton said that the criteria for appraising community coordination are realistic, that organized dentistry in Philadelphia is socially alert and responsible, that school dental programs are effective, and that the trend toward installation of public health dental clinics in school buildings is most promising.

In conclusion, he said that real progress has been made toward effective cooperation but that it would "be naive to claim that coordination is now 100 percent efficient, or ever will be." Coordination, he stated, is "a never-ending process, adapting to . . . the ever-changing constellations of new personalities, conditions, and experiences."

Chronic Illness Surveys To Include Dental Exam

Studies in Virginia to determine the extent and nature of the chronic illness problem will include a complete dental examination, according to Dr. David R. Wallace of the Virginia State Department of Health.

These studies, to be carried out by the State through local health departments, will ascertain the number of chronically ill and, in each case, the diagnosis, mobility status, need for medical care, and possibilities of rehabilitation. Only when such information is available can communities plan adequately to cope with chronic illness, Wallace stated.

Provision of dental care for the chronically ill often will take the dentist away from his private office, to a private home, a nursing home, a health center clinic, or a hospital, Wallace pointed out. The patients confined to their homes, he indicated, will present the greatest problem.

To illustrate the difficulties in providing a complete dental service for the chronically ill, Wallace mentioned problems associated with a few of the chronic diseases. In mental illness, he said, general anesthesia often must be used. In epilepsy, the dentist must avoid using removable bridges or dentures. When performing dental operations on patients with cardiac disease, special precautions must be taken.

Dental schools must train their students to cope with the dental problems of the chronically ill, Wallace advised. This might be done by giving students the opportunity of working with patients in hospitals and nursing homes. Special emphasis, he said, should be placed on such oral conditions as gingivitis, advanced periodontal disease, Vincent's infection, and recognition of the oral manifestations of such systemic diseases as tuberculosis, Addison's disease, nutritional disorders, diabetes mellitus, and oral cancer.

Wallace also recommended that the dental student become ac-

quainted with the procedures of multiphasic screening. This will enable him, he said, to share effectively in such a survey in his community.

New Apparatus Designed For Fluoride Recording

Two systems for continuous recording of the total fluoride content of a water supply were described by F. J. Maier and Ervin Bellack, who are with the Division of Dental Public Health, Public Health Service.

One newly designed apparatus combines double distillation with conductivity measurement. This apparatus isolates the fluoride ion from other interfering ions, Maier said.

A continuous record of the fluoride content, Maier explained, will not only serve as an indication of the operation of the fluoride-feeding system, but will provide a graphic history of the fluoride concentration at any previous time. Also, the recorder can be used as the primary device for actuating the fluoride-feeding mechanism, he stated.

The double-distillation apparatus is a further development of the single-distillation device described by R. D. Frazier and H. G. Oldfield of the Minnesota Department of Health. Their device, Maier said, gives a distillate satisfactory for direct chemical analysis of fluorides, but not for conductivity measurements.

With the double-distillation assembly, only those ions that distill over from the sulfuric acid used in the first still (chloride of nitrate, for example) are likely to contribute errors to the conductivity measurements. However, Maier pointed out, these may accumulate for some time in the second still before they appear in the final distillate. Thus, accurate determinations can be obtained by cleaning the apparatus and replacing the acid at appropriate intervals.

Except for daily changing of the

chart on which the conductivity is recorded and occasional replenishing of the ink used in the recorder, the unit may be allowed to operate continuously without attention for as long as the accumulation of ions in the first still will permit, Maler stated. For water containing relatively small amounts of dissolved solids, this may be as long as a month.

Rapid Colorimetric Method

The second apparatus Maler described combines continuous distillation with the rapid colorimetric method for measuring fluorides. The design of this apparatus provides for continuous metering of the water sample and two reagents, the mixing of the three ingredients, and the passing of the mixture through an absorption cell in a photometric device. A recorder, graduated in fluoride units, is connected to the photometer.

Incoming water, Maler said, can be distilled automatically and continuously by the apparatus described above. However, only one distillation is necessary because of the tolerance of the eriochrome cyanine R reagent to most interferences, he added.

Fluoridation in Grand Rapids Benefits Older Children

According to the results of the annual dental examinations in Grand Rapids, Mich., fluoridation has benefited not only children born since fluoridation was begun but also those born before, reported Dr. Francis A. Arnold, Jr., director of the National Institute of Dental Research, Public Health Service.

For 16-year olds, for example, the DMF rate decreased 26 percent between 1944 (the year before fluoridation was started) and 1954, he said. For children drinking fluoridated water continuously since birth, the percentage decrease ranged from 50 to 75 (see table).

The 1955 examinations of children

aged 11 through 16 years indicated that the beneficial effects of fluoridation continued on through the 11th year of fluoridation, Arnold added. Further reductions in the DMF rate were observed among children of each age.

At the same time, fluoridation in Grand Rapids has not produced a significant degree of dental fluorosis, Arnold pointed out. For 11-year olds, only 4 percent had even "very mild" fluorosis in 1955. None had a higher degree, and 89 percent were "normal."

This study, like many others, has demonstrated the certainty of fluoridation as a public health procedure for improving dental health of a community, he asserted. Moreover, he said, in none of the studies has there been any scientific evidence to suggest an adverse effect on other biological systems of the body.

Fluoridated Water Inhibits Caries in Erupted Teeth

A study of children in Grand Rapids and Muskegon, Mich., indicates that artificially fluoridated drinking water inhibits caries in teeth already erupted. The protective ef-

fect on teeth in the pre-eruptive stage has been established in earlier studies.

Although the protection given erupted teeth of a single individual is small, the total effect on a large number of people may have public health significance, stated Dr. Richard L. Hayes, Dr. Norman Littleton, and Carl L. White, of the National Institute of Dental Research, Public Health Service.

Between 1944-45 and 1956, Grand Rapids children experienced fewer and smaller cavities in approximal surfaces of first permanent molars than did Muskegon children, Hayes reported. The Grand Rapids children, he explained, had drunk fluoridated water since 1945, but the Muskegon children, only since 1951.

All the children studied had two or more first permanent molars in 1944-45 and were continuous residents of their respective cities. The two major study groups, each composed of 116 children, were matched for caries susceptibility on the basis of the 1944-45 examinations.

For statistical analysis, a system for scoring caries according to size or depth of the cavity or filling was used, Hayes stated.

On clinical examination, the size

Percentage decrease in caries rates after 10 years of fluoridation in Grand Rapids, Mich.

| Age (last birthday) | Number children examined | | Percentage reduction in caries rate | |
|---------------------|--------------------------|------|-------------------------------------|-----|
| | 1944 | 1954 | def | DMF |
| 6 | 1,789 | 561 | 54 | 75 |
| 7 | 1,806 | 751 | 48 | 63 |
| 8 | 1,647 | 567 | 43 | 57 |
| 9 | 1,639 | 477 | 35 | 50 |
| 10 | 1,626 | 515 | 17 | 52 |
| 11 | 1,556 | 499 | 2 | 54 |
| 12 | 1,685 | 260 | --- | 52 |
| 13 | 1,668 | 224 | --- | 48 |
| 14 | 1,690 | 250 | --- | 38 |
| 15 | 1,511 | 240 | --- | 35 |
| 16 | 1,107 | 198 | --- | 26 |

Mean caries scores for approximal surfaces of first permanent molars, matched groups of children in Grand Rapids and Muskegon, Mich.

| Examination | Grand Rapids | Muskegon | Difference |
|--------------------------|--------------|----------|------------|
| Clinical----- | 0.83 | 1.22 | 0.39±0.11 |
| X-ray----- | 1.73 | 1.99 | .26±.12 |
| Clinical plus X-ray----- | 1.74 | 2.02 | .28±.12 |

of the cavity or filling was recorded as small, medium, large, or "pulp exposure" and scored from 1 to 4. On X-ray examination, the depth was recorded as enamel only, or shallow, moderate, or deep dentin and scored similarly. A missing surface was scored 4. For each individual, the scores were totaled and divided by the number of surfaces at risk to give a "caries score."

The difference between the two groups of children in caries experience of approximal surfaces was evident from the clinical examination alone, from the X-ray examination alone, and from the two examinations combined (see table).

The difference in the mean caries scores for the buccal plus lingual surfaces, Hayes said, was about the same as the difference for the approximal surfaces. He considers this finding "curious" since the caries susceptibility of the two types of surfaces is very different.

The mean caries scores for occlusal surfaces was also lower for the Grand Rapids children than for the Muskegon children, although the number of decayed or filled occlusal surfaces was the same in the two cities, Hayes observed.

Periodontium Not Injured By Use of Fluoride Water

The use of fluoride-bearing water does not adversely affect the prevalence or severity of periodontal disease in children or adults, according to examinations of more than 20,000 persons, reported Dr. Albert L. Rus-

sell of the National Institute of Dental Research, Public Health Service.

In each of three comparisons between a group drinking fluoride-bearing water and a group drinking fluoride-free (or essentially free) water, the fluoride group exhibited the more favorable periodontal condition on direct examination, Russell said. Also, extractions because of periodontal disease were somewhat less frequent among adults in the fluoride communities.

One of the comparisons was between 144 adults aged 20-44 in Colorado Springs (2.5 p.p.m. F) and 379 adults in the same age group in Boulder (fluoride free), Colo. In Colorado Springs, 52.8 percent were free of periodontal disease as compared with only 38 percent in Boulder. Once it occurred, however, the

disease was equally severe in the two communities, Russell said.

For older adults, a comparison was made between residents of Bartlett (8.0 p.p.m. F) and residents of Cameron (0.4 p.p.m. F), Tex.; for children, between residents of Newburgh (1.0 p.p.m. F) and residents of Kingston (fluoride free), N. Y. The results were similar to those for Colorado Springs and Boulder.

Study of the question was also afforded by examinations of some 18,000 native and migrant children in communities using water containing about 1.0 p.p.m. F, according to Russell. Comparison of the native children with the migrants, he said, revealed no adverse effect of the fluoride water on periodontal health. In fact, there was a weak tendency for improved periodontal health among the native children with an increase in the length of time they had drunk fluoridated water.

The findings are "wholly incompatible with any hypothesis that the periodontal tissues of children or adults are harmed by use of a fluoride-bearing water," Russell concluded. However, he pointed out, they are not adequate to support a hypothesis that fluoride water results in improved health of periodontal tissues.

Safety . . .

Farm and Home Safety Needs New Approach

To emphasize the need for farm and home safety programs, Dr. Charles M. Cameron, Jr., acting chief of accident prevention for the North Carolina State Board of Health, pointed out that in the past 5 years more than 100,000 Americans have lost their lives in their homes. Farming as an occupation, he said, ranks first in number of deaths from accidents.

Although a great number of safety

programs have been initiated in the past few years, recent surveys indicate that there is a need for still greater awareness on the part of public health workers that accidents are a crucial health problem. An inventory made by the National Safety Council in 1955 listed 591 agencies that had carried out some type of home safety activity in the previous year. Public health agencies were far outnumbered by farm groups, women's clubs, safety councils, and other organizations.

More safety education on a face-to-face basis is needed, Cameron as-

Death Rates for Accidents

Were it not for motor-vehicle accidents, rates of death from accidents per 100,000 population could have shown a marked decline since 1910. Motor-vehicle accident death rates, about 24 deaths per 100,000 population in 1953, declined from an average of 8.9 deaths per 100 million miles in 1938-42 to 4.5 in 1953. (PHM chart)

serted, suggesting that this process is especially suitable for public health workers, who have gained an intimate understanding of the individual and his family.

Traditional safety activities, according to Cameron, have included short-term campaigns, safety drives, and promotional programs utilizing the media of public information—pamphlets, booklets, posters, newspaper articles, radio spot announcements, and safety proclamations.

Has anyone attempted to determine just which of these efforts actually do change human behavior toward safer living? he asked.

Admittedly, he said, it might not have been wise to delay public health safety programs until we could answer this question, but certainly every effort should be made to answer it as soon as possible.

Greater cooperation by administrators, public health nurses, sanitarians, and health educators is another need in accident prevention work, according to Cameron. It was apparent early that all public health disciplines would be essential if accidents were to be attacked successfully, and many local health departments initiated accident control activities on that basis, he said. However, in some departments, home safety is considered a nursing activity or the exclusive responsibility of the health educators. The labeling of any program as the distinctive property of a single discipline does not, he concluded, stimulate interest among the others.

Failure to utilize fully all community safety resources has further hamstrung many health department accident prevention programs, Cam-

eron said. Industrial safety programs, community safety councils, municipal fire departments, and agriculture extension programs have been repeatedly cited as valuable allies in planning and conducting meaningful safety programs, yet the location and facilities of these are unknown to many public health workers.

The role of the local health department as impartial coordinator of all community safety interests he envisioned as another of the unique contributions public health can make to the safety movement.

Automobile Accidents Related to Mileage Driven

The more miles a person drives, the more likely he is to have an accident, according to a home interview study of 810 drivers in Schenectady, N. Y. This result from one phase of a research project on driver behavior and accidents was reported by Dr. Jean K. Boek, Russell Sage College, Albany, N. Y.

Another finding was that men tend to have more accidents than women, even when the factor of exposure (number of miles driven) is held constant. In fact, Boek said, the percentage of men in the low exposure group who had accidents was higher than the percentage of women in the high exposure group.

Age, weight, schooling, usual speed on the open road, drinking, and smoking were other characteristics on which Boek reported. She compared drivers who had no accidents, those who had accidents for which they were responsible, and those who had accidents for which they were not responsible.

In another phase of the project, Boek said, no relation was found between "unsafe" driving and being in accidents, nor were there any significant age or sex differences in driving behavior. In this part of the study, which covered 550 drivers, nine driving acts, such as stopping and turning, were observed without

the drivers knowing it and scored "safe" or "unsafe."

This research, Boek concluded, indicates the importance of giving careful attention to measurement of exposure to accidents, of studying men and women drivers separately, and of studying a random sample of drivers in their communities so that variables may be observed as they actually operate.

Support Driver Education Health Officials Asked

A five-point program to improve the behavior of automobile drivers was proposed by Dr. Herbert J. Stack, director of the center for safety education, New York University. Underlining the urgency of the problem, he asserted that bad driving practices caused about 80 percent of all traffic deaths last year.

Stack appealed to health authorities to ally themselves with the traffic education phase of the safety movement. "The accident prone could be thought of as sick drivers," he pointed out. State and local health departments, already cooperating with the home safety campaign, will make a valuable contribution by extending their interest to traffic safety education, he stated.

Accidents are caused chiefly by faulty attitudes and bad personality characteristics rather than by a lack of driving skill, he said. New York University studies show that social irresponsibility is the worst offender.

Experience has proved that improved, accelerated enforcement and a strengthened police force will reduce accidents, Stack said, but the gigantic task of effectively regulating 65 million drivers on our thousands of roads calls for more than police efforts.

He urged uniform motor-vehicle rules of the road, regulations, and driver's license laws, pointing out that many States issue driving licenses almost as freely as they do hunting permits. He commended the 14 States using the point system

with a graduated scale of demerits. Stack also praised driver behavior clinics. License revocation and suspension are the most efficient sanctions in the driver improvement program, he said.

Traffic engineering undoubtedly contributes toward good road behavior. Devices such as medial strips on four-lane roads, channelizing traffic, and information and warning signs reduce human error substantially.

Strengthening the work of the traffic courts, according to Stack, is essential. Lack of uniformity and of trained magistrates, overcrowded sessions, and poor conduct of many courts foster a negative attitude toward traffic control.

Education

Stack pointed out that most drivers acquired their skills in commercial driving schools, or haphaz-

ardly from friends or relatives, with little direction in proper driving attitudes. However, the driver education movement in the Nation's high schools trained nearly 1 million students last year. The State of Michigan, moreover, will now require license applicants under 18 years old to have completed an approved course. Other States will soon follow, Stack believes.

Automobile dealers have cooperated by lending more than 6,000 cars without cost. Stack also mentioned the contribution of more than \$200,000 from casualty insurance companies and oil firms for teacher scholarships, and the endorsement of the driver education program by well over 80 organizations.

Educating the mass of adult drivers, most of whom appear to be satisfied with their performance, constitutes the greatest challenge.

Environmental Health . . .

Food Poisoning Outbreaks Traced to Milk Powder

Spray-dried nonfat milk solids were implicated in a series of 19 outbreaks of acute gastroenteritis among Puerto Rican school children early in 1956.

Reporting the epidemiological work in tracing the source and agent were Dr. Rolando Armijo of the University of Puerto Rico School of Medicine, Dr. Rafael Timothee of the Puerto Rico Department of Health, and Dr. D. A. Henderson and H. B. Robinson, both of the Public Health Service.

The outbreaks, the first associated with spray-dried milk in the United States, occurred between January 23 and February 21 in 16 schools participating in the school lunch program. More than 775 children became ill.

Food histories of the school chil-

dren suggested spray-dried milk as the responsible food. Confirmation was achieved by a human volunteer experiment.

Milk powder remaining in an opened can that was obtained the day following one of the outbreaks was reconstituted and given 13 adult volunteers by random selection. Nine of them developed gastroenteritis symptoms, five to a marked degree. Of the 13 controls given commercially purchased milk powder, only 2 developed mild symptoms.

Clinical symptomatology and the incubation period pointed to staphylococcal enterotoxin as the responsible agent. The principal symptoms were nausea, vomiting, abdominal pain, and diarrhea without fever, beginning from 1 to 5 hours following the noontime school lunch. There was virtually complete recovery within 24 hours.

The negative bacteriological results eliminated the staphylococcal organism itself. Toxicological tests

for metallic poisons were also negative.

That enterotoxin was present in the dried milk prior to reconstitution was adduced from the fact that the volunteers drank the milk almost immediately after it was made. And in none of the 16 schools was the reconstituted milk allowed to stand more than 5 hours before serving. In 9 of the schools the time interval was 2 hours or less.

Three lots of milk powder from 1 of the 8 processing plants involved were indicated as the responsible source of the outbreaks through a detailed epidemiological search, complicated by the lack of adequate identification on the individual cans. Bacteriological plate count records of samples from this plant were shown to be clearly out of line with those obtained from other plants.

Review Processing Criteria

The report emphasized the need for a careful review of the methods of processing and testing the milk and labeling packages in view of the substantial quantity of spray-dried milk produced and its worldwide distribution. The Puerto Rican school lunch program now uses some 4 million pounds a year.

Under the present testing procedures samples of all dried milk processed are submitted to the dairy inspection laboratory for plate analysis before release for distribution, the report related. But it pointed out that with only one test made for each 15,000 to 20,000 pounds of powder produced, a contaminated batch might escape detection. The testing lots are obtained by pooling 4 to 5 samples.

In suggesting consideration of the validity of the plate count itself, the report cited the plate count of but 30,000 colonies per gram for the milk used in the human volunteer experiment, a figure ordinarily certifying the milk as extra grade. It was pointed out that the heat to which the milk is subjected in the drying process might, in fact, reduce the bacterial flora to this level without destroying the enterotoxin.

Federal-State-Local Units Set Water Resources Policy

Forecasting growing demands on our water resources, Roy W. Morse, Department of the Interior, and staff member of the Presidential Advisory Committee on Water Resources Policy, reviewed recommendations of the committee to meet these demands.

In many parts of the western United States, the water supply has always been critical while in the more eastern part an ample supply has usually been taken for granted, Morse said. The New York City shortage in 1970 made many people aware of the dangers of a general water shortage situation.

Water Supply

Morse divided water supply into four major categories: public water supply, including domestic, commercial, and industrial use; self-supplied industrial use; steam electric power; and irrigation. These, he said, account for 98 percent of the total use.

Basic to the growing demand for water is the growth in population and the increased consumption per capita since World War II. Of the more than 200 million population predicted for 1975, approximately three-fourths will be served by public water supplies, Morse estimated. The daily water demand will rise from 17 billion gallons to an estimated 30 billion gallons. Further, it is estimated that \$1 billion a year during the next two decades will be required to eliminate present deficiencies, offset obsolescence, and adequately serve the growing population.

Demand for self-supplied industrial water has grown faster than demand for public use, Morse told the engineers. New processes require increasing quantities of water, about 60 billion gallons a day at present.

By 1975, steam electric plants are expected to require 120 billion gallons a day, twice the volume of the

present use, largely for cooling, Morse said.

Irrigation will require about 170 billion gallons per day by the same date. The usable return flow ranges from 20 to 60 percent, he said.

With adequate planning and with adequate acceptance of the many opportunities for increased water use, this future demand can be met. The greatest problems will be those resulting from unequal distribution of our national water resources.

Endorsing the objectives formulated by the Presidential Advisory Committee on Water Resources Policy, Morse said there are many approaches to the same end. Some would seek greater Federal authority while others fear Federal interference and dislike any assistance. The committee, he said, concluded that the desirable course lay between these two extremes. Thus, while it is desirable to have national policies where feasible, the committee believes water problems can be solved best in cooperation with the States and local interests. Sound procedure requires that all interested groups participate in planning from the beginning, Morse emphasized.

Recommendations

After reviewing the activities of the Federal agencies, their histories, and the laws under which they operate, Morse said the committee offered these recommendations:

1. More cooperation and coordination of water resources development among Federal agencies.
2. Adaptation of water resources policy to regional and local needs.
3. Sharing of financial responsibility for water development among Federal, State, and local governments, and private interests.
4. Equal contribution for equal benefits received.
5. Recognition of water rights as property rights in determining the disposition of water.
6. State control of pollution at the source; joint State action in solving interstate problems; and Federal research, investigation, and technical assistance.

The committee urged that the program of water quality evaluation be strengthened. Today there is no coordinated program for measuring biological quality, and there are only 220 stations throughout the country where daily samples for determination of chemical quality are taken, Morse reported.

Only in recent years, he said, has adequate attention been given to municipal and industrial water supplies or the provision of minimum stream-flow for pollution control. Individual cities and private companies have made their separate plans, often with little thought for the effect on other people, utilities, or industries. As a consequence, these features of multipurpose projects have not received the attention they deserve.

To meet the need for sound planning, the committee recommended the establishment of river basin committees including representatives of the Federal agencies and each affected State, with a nonvoting chairman appointed by the President; an office of coordinator of water resources in the Executive Office of the President; and an impartial board of review for evaluating the economic and engineering feasibility of projects before their submittal to the President.

The committee, Morse said, also recommended a study by the Federal Government in collaboration with the States to determine the relationship between the establishment of property rights to water and the economic and social development of the Nation. Such a study would clarify the rights of the respective parties, an essential to solving the current dilemma in this field.

San Francisco Intensifies Air Pollution Control

Determined to control present and future air pollution as the concentration of people and their activities increase, the San Francisco Bay area has embarked on a program of air pollution control that necessi-

tates extensive integration with many types of government agencies at several levels—city, county, State, and Federal.

Designing the administrative and technical program for the first multi-county air pollution control district in the United States is the job of Benjamin Linsky, former smoke abatement officer for Detroit.

Linsky urged prompt action by communitywide cooperation. Fresh air has to be paid for in money and effort, he said.

In his talk to the Conference of Municipal Public Health Engineers, he opposed previous impressions that air pollution programs can be handled, like industrial hygiene, on a confidential relationship with employers only, or like water pollution control, where only a few agencies, industries, or home owners are directly responsible, or like traffic safety programs, where few drivers feel personally vulnerable.

Asked to explain why he believes administration of air pollution control differs from all other programs for public improvement, Linsky gave the following reasons.

1. The range of ownership of potentially polluting property is wide. It includes owners of factories, automobiles, homes, apartment homes, and of general commercial enterprises plus transportation companies, agriculturalists, scavengers, scrap and salvage processors, and government agencies.

2. The number of property and equipment items that emit pollutants directly to the atmosphere is about as large as the number of adults in the area. (This means 1 home plus 1 car for every 2 adults per family, modified downward by multiple dwellings and upward by governmental and commercial industrial operations and increased automobile duplication, he said.)

3. Many effects of excessive air pollutant concentrations are readily observed by large numbers of adults, who are directly affected in their person, property, or activity, but the subtle effects arouse their fears be-

cause they are not so readily detected.

4. The similarities of some of the technical measurement methods to those of other programs have led practitioners trained in other fields to conclude that the new administrative problems are solvable by the old familiar methods.

5. The many academic and scientific disciplines in air pollution control have not been welded into an accepted pattern of terminology, education, or training other than the "buddy" system, a combination of apprenticeship and internship.

6. The patterns of legislative design are not frozen for multiple community areas, enforcement and rule-making procedures, or technical methods to be adopted.

7. Present budgetary need can only be approximated by comparison with tasks and budgets of other air pollution control programs. The wide difference in community standards, tasks performed, and administrative philosophies, ranging from pure persuasion to rigorous court enforcement, makes skill and judgment necessary.

Typhoid Outbreak Source Eludes Investigators

The typhoid fever outbreak in the midwest in 1956 should alert sanitarians to the need for increased vigilance in food sanitation, declared Frank L. Woodward of the Minnesota Department of Health.

If there was a common source of infection in this outbreak, in which at least 6 midwestern States were affected, it must have been some food with interstate distribution, he maintained.

Intensive epidemiological investigation failed to find a "single most likely source," he said, but the evidence, he believes, points to contaminated food shipped interstate. This conclusion is his own, drawn from incomplete, unofficial memorandums, not necessarily that of the investigators, he stated.

Unlike most disease outbreaks, there was no immediate evidence of a relationship between any two of the cases, according to Woodward. There were no two cases in a family or among acquaintances and no common point of assembly, he said. There were no multiple primary cases and apparently no secondary cases.

To illustrate how various factors influence the course of an investigation as an outbreak progresses, he outlined developments in Wisconsin, Iowa, and Minnesota from January through mid-July.

Since the first cases occurred in early January, Woodward said, Christmas-season foods were first considered as a possible source of the infection—chocolated-covered cherries, a hand-finished product, for example. But as new unrelated cases developed in February and March, attention was directed to all foods.

Woodward considers it a likely possibility that a particular food was continuing to be contaminated, probably intermittently, throughout the period. This concept, he said, suggests, among other items, fresh vegetables, such as lettuce and celery.

The outbreak furnishes a challenge to all persons responsible for sanitary control of food production, processing, and marketing, Woodward concluded. Food ingredients as well as finished food and even wrappers and containers require scrutiny, he said.

High Free Residual Chlorine Effective for Pool Waters

The use of high free residual chlorine in swimming pools disposes of the need for standard bacterial tests, according to Dr. Elizabeth D. Robinson and Louise R. Elliot of Smith College, and Eric W. Mood of Yale University.

Tests conducted on samples from four swimming pools under varying conditions show that high free re-

sidual chlorination produces water free of pathogenic bacteria. If accurate titrations of the chlorine residuals are carried out routinely, they stated, bacterial standards need not be used to determine the safety of swimming pool water.

This new concept grew out of a search for a procedure that would keep pace with the latest developments in swimming pool water treatment. "Accepted bacterial tests," they said, "are not sufficiently delicate or precise to determine the relatively few organisms which survive high free residual chlorination."

Such chlorination, a relatively new treatment in the United States, is effective even during peak swimming loads and is easy to maintain. Also, they pointed out, free chlorine residuals eliminate the chance that a swimming pool will transmit bacterial disease. Levels of chlorination can be almost immediately ascertained, but bacterial tests may take 48 hours or more.

Claims Dishwashing Devices Remove Sticky Viruses

Home dishwashing machines maintained at the recommended water temperature of 150° F., or above, effectively and consistently removed all detectable influenza A, mumps, herpes simplex, vaccinia, poliomyelitis, and T₁ bacteriophage viruses from dishes excessively contaminated in the laboratory, according to studies reported by Dr. S. Stephen Chapman and Barbara Vinsel of the School of Medicine, University of Louisville.

A sensitive swab technique for detecting viruses on dishes was developed. It was found, using this method, that influenza A, herpes simplex, and mumps viruses remain viable on soiled dishes for at least 24 hours.

Chapman and Vinsel claimed that influenza and mumps viruses were not effectively removed by the usual home, hand-dishwashing manner, stating that the success of viral

elimination was quite variable, however fastidious the person washing the dishes.

Optimal sanitizing of viral-contaminated dishes resulted when water temperatures of multiple-rinse home dishwashers were 150° F. and above. Detergents added in both prerinse and wash cycles promoted quickest removal of the viruses. It was apparent that certain basic dishwasher design features were important for rapid virus removal.

Sanitation, Water Supply Stressed by India

Projects to improve India's water supply and sanitation have been given priority since they are vital to the success of the new republic's broad health program, reported Callis H. Atkins, regional engineer, Public Health Service. He served with the U. S. Technical Cooperation Administration as adviser in public health engineering to the Indian Government from 1952 to mid-1955.

Each year, in the 10 years ending in 1950, about 2 million persons died and 50 million became ill from diseases borne by water and filth, according to an estimate cited by Atkins.

A survey in 1949 by a committee appointed by the Ministry of Health attests to the huge tasks facing India. Only 16 percent of the towns had protected water for 6 percent of the population. The percentage for villages was even lower. There were sewers in 23 cities out of 48 with populations of 100,000 and over. In the villages, less than 5 percent of the homes had any kind of latrines.

Project Planning

Impetus for the environmental health projects came, Atkins pointed out, during India's first 5-year plan, which was designed for comprehensive development of the country's social and economic resources. Health projects were set up in se-

lected areas under the Community Projects Administration.

A survey disclosed that there were 50 engineers with graduate training in public health or sanitary engineering. There was no sanitary engineering or public health engineering unit in the national government, although a few states had small organizations. Local production of sanitation equipment was insufficient, making importation necessary.

Funds allocated to the Community Projects Administration for water and sewerage were small, but some states had limited amounts for that purpose. At this point, Atkins said, the Technical Cooperation Administration offered its assistance, and the United Nations International Children's Emergency Fund and the World Health Organization showed interest in taking part.

Operation of the Projects

In August and September 1954, India announced it would aid its states in building water supply and sanitation facilities. About \$13 million was offered for passing on as loans to municipalities within 1½ years, but 6 months later the fund had increased to \$42 million, allocated to about 250 municipal projects.

For rural work about \$6½ million were first channeled to the states on a matching basis. This rose to more than \$13 million, a large share being distributed to approximately 100 projects in about 10 thousand villages during the first year. Assistance from the Technical Cooperation Administration, representing 5 percent of total cost, was in Atkins' opinion the catalytic agent in the program's development.

Research and training in water supply and sanitation were accelerated and the scope broadened through the cooperation of the Ford Foundation, the World Health Organization, the Rockefeller Foundation, and the Technical Cooperation Administration.

When possible, equipment and

materials were purchased locally to stimulate the country's industry. Indian production of cast iron pipe rose to about 50,000 tons a year, Atkins pointed out, over half the quantity needed. With TCA funds, a large number of trucks, jeeps, pumps, and some engineering equipment were imported.

Public health engineering sections were organized in the Central Ministry of Health and in many states previously without such units. The states in turn charged new district engineer offices and resident engineers in the municipalities with all urban work; for rural operations, the state appointed a public health engineer to head a technical staff for each project. Staff duties included health education and construction of water supplies and latrines. After completion of the project, one sanitarian was to remain for maintenance and general sanitation.

In May 1955 India was looking forward to the fulfillment of 250 urban projects scattered through 17

states, and 100 rural projects in 16 states.

Atkins said that extension of the program is planned under the second 5-year plan beginning in 1956, under which about \$135 million has been earmarked for city water supply and sewerage loans, and \$62 million for rural projects. The new plan includes funds for training 1,000 engineers, 200 chemists and biologists, and 5,000 sanitarians and allied personnel; as well as funds to support research programs.

In Atkins' opinion the present and projected programs should satisfy major municipal needs in about 25 years, and rural requirements in 50 years if economic conditions remain at the 1955 level. It may well be, however, that simultaneous advances in all phases of the resources development program will cause "geometrical instead of arithmetical progress," bringing India considerably closer to her goal of safe water supplies and a high level of sanitation.

Radiological Health . . .

Data on Radiation Injury Sought for Standards

Plans to expand Public Health Service activities in radiological health were announced by Dr. Clinton C. Powell, who is developing for the Service a program on the medical aspects of radiation.

Parallel to broad environmental control, which is also being expanded, the Service will undertake epidemiological investigation of the quantitative aspects of low-level radiation hazards and other medical research.

To set realistic, yet safe, standards, Powell said, scientists need much more data, especially for humans, on the amount of radiation injury occurring in the population.

Genetic effects, increased inci-

dence of neoplasms, including leukemia, and premature aging must be considered in establishing radiation exposure standards.

Experience to date, Powell reported, indicates that harmful effects of chronic low-level radiation exposures will be delayed for years, or even generations. Since most of these harmful effects will probably be no different qualitatively from disease conditions already present in the population, we must study statistically the incidence of these conditions in exposed and unexposed groups if we are to detect any increase resulting from radiation exposures.

Genetic mutations, he said, are irreversible and have no threshold for their production. Furthermore, the total number of mutations will be

the same for a small dose delivered to a large number of persons as for a large dose delivered to a small number. Thus, a radiation dose must be reduced in direct proportion to the number of reproductive persons involved if the total genetic consequences are to remain constant.

Therapeutic Doses

In the healing arts, he said, there has been an increasing awareness of the possible risk to the patient in diagnostic and therapeutic medical uses of ionizing radiation.

Exposures that might have been acceptable if no other environmental exposure were added now require reevaluation in the light of the total actual and potential exposure that the entire population may receive.

Powell pointed out that a fixed or arbitrary limit on medical radiation exposures would be unrealistic. Circumstances vary so widely in each individual case that the decision in each case must rest with the practitioner. However, he said, the information available to date does not allow the practitioner to make a firm estimate of the possible hazard.

Terming it axiomatic that any exposure should be reduced to the lowest level consistent with good diagnosis or therapy, he designated three immediate measures in equipment and operation, if they are not already employed.

Proper added filtration, he said, collimation of the beam by the use of proper cones, and use of optimal factors, such as higher kilovoltages, can reduce the dose to the patient in many instances and at the same time actually improve the diagnostic quality of the study.

Measuring Radioactivity In Water and Soil

Practical procedures for determining the gross alpha and beta radioactivity of water, soil, and biological samples were presented by Dr. Lloyd R. Setter, G. Richard Hagee, and Dr. Conrad P. Straub of the

Robert A. Taft Sanitary Engineering Center, Public Health Service.

The procedures described have applied to surface and ground water throughout the United States during the past 6 years.

They consist of separating the suspended activity by filtration and evaporating the filtrate. The filter and concentrated filtrate samples are placed in separate dishes 2 inches in diameter and dried at 103° C. or ignited at 600° C.

The samples are inserted in a radiation detector called an "internal proportional counter." The detector consists of a methane-argon gas counting chamber, a preamplifier, an electronic scaler, and power supply assembly. For detection, the radiation escapes from the sample, enters into the sensitive volume of the counting chamber, and ionizes the counting gas. The scaler totals the ionization events occurring during a selected time interval.

The detectors have a maximum efficiency of about 50 percent for alpha and 65 percent for beta activity from 1-year-old fission products.

The methods used are suitable for estimating nonvolatile radioactivity at levels below 100 micromicrocuries per liter, the maximum permissible concentration of unknown radionuclides in drinking water. They are applicable at levels exceeding 100

µµc. per liter and may, through decay measurements or a knowledge of radionuclide composition, indicate the health significance of observed activity.

Methods of identifying and determining radionuclides absorbed by soil were described by Bernd Kahn, chief chemical engineer of Sanitary Engineering Center Activities at the Oak Ridge National Laboratory.

Radionuclides are either leached from soil or dissolved with the soil, then separated and purified by radiochemical procedures, and counted with a radiation detector that has been calibrated for counting efficiency.

Kahn presented the leaching procedures for radiocobalt and for radionuclides of the major fission products cesium, strontium, cerium, yttrium, zirconium, niobium, and ruthenium.

He reported that these methods of soil analysis have been largely confined to Atomic Energy Commission installations because of widespread unfamiliarity with radiochemistry. But their similarity to common chemical analyses should broaden their use.

The increased distribution of radionuclides by fallout and by waste discharges has created the need to study the behavior of radionuclides in the environment, he said.

Communicable Diseases . . .

Strep Carrier Rates High In Nashville Children

In view of the scarcity of epidemiological data on streptococcal infections in civilian populations, Drs. Robert W. Quinn, Floyd W. Denny, and Harris D. Riley are studying preadolescent children in three Nashville, Tenn., public schools.

They report extremely high car-

rier rates of hemolytic streptococci for the children, all normal third and fourth graders, during the first 2 years of study.

Dr. Quinn and Dr. Denny, professors of preventive medicine at Vanderbilt and Western Reserve Universities, respectively, and Dr. Riley, instructor in pediatrics at Vanderbilt, reported the following:

Group A streptococci composed 84 percent of all streptococci recovered.

Fifty-two percent of these strains were typable.

The schools selected for study are in differing socioeconomic areas. Children in one school come from relatively spacious homes where the educational attainments are higher and heating and toilet facilities are better. Carrier rates for this school reached 60 and 42 percent for the study years, 1953-54 and 1954-55.

In the two schools drawing from poorer environments, the rates were not so high, 45 and 26 percent in one, and 41 and 30 percent in the school serving an inferior area.

Possible explanations for the high carrier rates and their differences in the schools and between study years were explored. Meteorological conditions in Nashville were ruled out. And neither environmental factors in the schoolrooms nor in the homes seemed to affect the carrier rates directly. In noting that the presence or absence of tonsils among the children had little apparent effect on the carrier rates, they concluded that more data are needed on this particular characteristic.

Psittacosis a Health Hazard in Oregon Poultry Industry

Psittacosis is increasing in importance as a hazard to poultry workers on farms, in rendering and processing plants, and in poultry marketing facilities, according to Dr. Harold M. Erickson, Oregon State Health Officer, and his associates, Dr. Samuel B. Osgood and Dr. Monroe A. Holmes. They feel that its occurrence in poultry may be of equal or even greater significance to man than the infection in psittacine birds.

In 1956, 86 persons, 27.8 percent of the 309 workers exposed to infected turkeys, became ill with psittacosis in Oregon, Erickson reported. Twenty-eight required hospitalization and two died. Five worked on farms, and the remaining 81 were employed in processing and marketing operations.

How the disease is transmitted in poultry, particularly turkeys, is not known, Erickson stated, but it may be airborne. In a rendering plant, aerosol studies demonstrated tracer bacteria in air samples collected both inside and outside the plant; in a processing plant, inspectors and other workers, as well as those defeathering and eviscerating birds, became ill.

He suggested precautions to minimize the danger of contracting psittacosis. These included antemortem veterinary inspection of all birds, elimination of sick birds from flocks, quarantining of flocks with suggestive symptoms, treatment of infected flocks with tetracycline compounds, strict environmental control in processing plants, postmortem veterinary inspection and condemnation of suspicious birds, rigid personal hygiene and use of rubber gloves and masks by poultry workers, and prompt medical attention to unusual respiratory or pneumonia-like illness in poultry workers.

Erickson stressed the need for research. Until the disease in poultry flocks can be recognized early and controlled promptly, it will be of real significance in occupational health. Psittacosis is also of sufficient economic importance to warrant large expenditures for research and epidemiological investigations, as well as for environmental control, he said.

Texas Q Fever Study Finds Ticks Negative

In an enzootic and endemic area, tests for Q fever vectors among ticks and other arthropods were negative, according to Drs. J. V. Irons, R. B. Eads, and J. E. Peavy, of the Texas State Health Department.

The finding was part of a study covering 64 confirmed human cases and infection in 8 dairies in south Texas in the period from September 1948 through December 1955. The majority of Q fever cases occurred in men living on farms or in towns in southern Texas, where most of the

livestock infection was also centered. Circumstances pointed to cattle as the most probable infection source, they concluded, sheep and goats being of minor importance. The search for possible modes of transmission pointed to the drinking of raw milk or inhaling the dust near cattle trucks, barns, and pens.

For diagnosis of the 64 cases, clinical, epidemiological, and laboratory findings were used. The complement fixation test was the most valuable as a diagnostic and epidemiological aid.

The concentration of Q fever in south Texas, mainly in Kleberg and adjacent counties, and the failure to find the causative agent, *Coxiella burnetii*, in many pools of ticks in that area indicate a need for further investigation.

New Bovine Viral Agents Isolated in Michigan

Eight strains of a filterable, cytopathogenic agent were isolated from 52 apparently healthy dairy cattle in Michigan, reported Dr. Calvin M. Kunin of Peter Bent Brigham Hospital in Boston, Mass., and Elva Minuse of the School of Public Health, University of Michigan.

The strains, which are related serologically, do not resemble other human or bovine agents studied.

Cattle kidney tissue culture was the medium used for isolation, which was accomplished, they said, with relative ease. The group of strains was tentatively designated ECBO (enteric, cytopathogenic, bovine, orphan) because their isolation strikingly parallels that of the Coxsackie and ECHO viruses from healthy humans.

The agent produces lesions and multiplies in tissue culture, suckling mice, and chick embryos. When grown in the amniotic sac of 10- to 11-day-old Barred Rock eggs, the agent dwarfed the embryo, denuded the feathers, and released melanin granules into the amniotic fluid.

Antibodies to the agent were not

the same for a small dose delivered to a large number of persons as for a large dose delivered to a small number. Thus, a radiation dose must be reduced in direct proportion to the number of reproductive persons involved if the total genetic consequences are to remain constant.

Therapeutic Doses

In the healing arts, he said, there has been an increasing awareness of the possible risk to the patient in diagnostic and therapeutic medical uses of ionizing radiation.

Exposures that might have been acceptable if no other environmental exposure were added now require re-evaluation in the light of the total actual and potential exposure that the entire population may receive.

Powell pointed out that a fixed or arbitrary limit on medical radiation exposures would be unrealistic. Circumstances vary so widely in each individual case that the decision in each case must rest with the practitioner. However, he said, the information available to date does not allow the practitioner to make a firm estimate of the possible hazard.

Terming it axiomatic that any exposure should be reduced to the lowest level consistent with good diagnosis or therapy, he designated three immediate measures in equipment and operation, if they are not already employed.

Proper added filtration, he said, collimation of the beam by the use of proper cones, and use of optimal factors, such as higher kilovoltages, can reduce the dose to the patient in many instances and at the same time actually improve the diagnostic quality of the study.

Measuring Radioactivity In Water and Soil

Practical procedures for determining the gross alpha and beta radioactivity of water, soil, and biological samples were presented by Dr. Lloyd R. Setter, G. Richard Hagee, and Dr. Conrad P. Straub of the

Robert A. Taft Sanitary Engineering Center, Public Health Service.

Communicable Diseases . . .

Strep Carrier Rates High In Nashville Children

In view of the scarcity of epidemiological data on streptococcal infections in civilian populations, Drs. Robert W. Quinn, Floyd W. Denny, and Harris D. Riley are studying preadolescent children in three Nashville, Tenn., public schools.

They report extremely high car-

rier rates of hemolytic streptococci for the children, all normal third and fourth graders, during the first 2 years of study.

Dr. Quinn and Dr. Denny, professors of preventive medicine at Vanderbilt and Western Reserve Universities, respectively, and Dr. Riley, instructor in pediatrics at Vanderbilt, reported the following.

Group A streptococci composed 84 percent of all streptococci recovered.

male stomach cancer death rates in Boston, in which "Russian born" males (including those born in Poland) had the highest rates. The report also notes that Buffalo's large Polish population does not explain why a greater proportion of the stomach cancer cases than of the controls were born in Poland, since both stomach cancer and control groups included the same proportion of Buffalo residents.

High Blood Pressure Raises Risk of Heart Attack

Men between 45 and 62 years of age with high blood pressure appear to stand a much greater risk of developing heart attacks than other men, affirmed Drs. Thomas R. Dawber, Felix E. Moore, and George V. Mann, National Heart Institute, Public Health Service.

Other factors which may have a probable relationship are obesity, high blood cholesterol, liver disease, and chronic arthritis, and rheumatism, they said in reporting preliminary findings from data accumulated during the first 4-year followup period in a long-term epidemiological study of heart disease at Framingham, Mass.

The community is being observed over a long period to discover how many people have heart disease, what types they have, when it develops, and what factors seem to be associated with it. More than two-thirds of a random cross section of Framingham residents between 30 and 60 years of age were given a complete, initial physical examination during 1948-52, and are being reexamined at 2-year intervals.

Comprehensive data are recorded on all conditions which medical scientists suspect may be related to the development of heart disease. Comparable data collected from both those who remain free of heart diseases and those who subsequently develop them are then analyzed to disclose what factors may be related to the development of disease.

Fifty-two of 900 men between 45 and 62 years of age developed coronary heart disease during the first 4-year followup period. This limited number permitted only tentative conclusions.

High blood pressure and hypertensive cardiovascular disease were found to be strongly associated with the development of coronary attack. High incidence rates in participants with high blood pressure were closely correlated with electrocardiographic patterns consistent with left ventricular hypertrophy.

Obesity appeared clearly related to the risk of coronary attack. The upper 10 percent of overweight men showed an attack rate three times as great as men whose weight was below the median.

Liver disease appeared to increase the risk of coronary attacks as did the presence of chronic arthritis and rheumatism.

Socioeconomic status seemed to have little relationship to the risk of developing coronary heart disease. Persons with grade school education did not have significantly

higher rates than the group as a whole.

The incidence of coronary disease showed a correlation between sex differences and amount and severity of disease. A 4-year rate of 12 per 1,000 was observed among men 30 to 44 years of age, while no new cases of disease were found among women in this age group. The 4-year incidence for men 45 to 62 years of age was 58 per 1,000, exactly double that observed among women. Significantly, more than one-fourth of the coronary disease cases among men within the followup period were fatal; most of the deaths occurred suddenly before the patients could be hospitalized.

Limitation of Interviews Noted in Illness Survey

The prevalence of chronic diseases as measured by household interviews and by clinical examinations was compared statistically in the Baltimore chronic disease survey

Deaths from Chronic Diseases Increase

Reported causes of death indicate that fatalities from acute infectious diseases are declining almost to the vanishing point. On the other hand, deaths caused by chronic noninfectious diseases seem to be almost as frequent as those formerly caused by infections. (PHM chart)

observed in human or porcine gamma globulin, nor in serum from three farmers in close contact with the infected herd. Such antibodies were found, however, in 90 percent of the herd from which 7 of the 8 strains were isolated.

They speculated that these findings when considered together with the known neutralizing activity against type 2 poliomyelitis virus present in the serum of many cattle may indicate that poliomyelitis-related viral agents will be isolated in the future by similar methods.

Global Campaign Progress Against Malaria Cited

World malaria incidence has dropped by tens of millions in the last few years under the impact of residual toxicants applied nationwide by many countries, reported Dr. Paul F. Russell of the Rockefeller Foundation. But malaria remains a major global disease, he said, probably causing 200 million clinical cases and 2 million deaths last year.

Thus far, energetic measures have erased the disease from wide areas, and its grip on several once highly malarious countries has been broken. The goal of world malaria eradication is no longer utopian, he stated.

Eradication campaigns have four phases, he explained: the preparatory phase, the phase of attack, the phase of consolidation, and finally, the phase of maintenance.

To illustrate the workability of such campaigns, Russell outlined the eradication process in several countries. In Venezuela, DDT residual spraying has removed the disease from all but a few residual foci; in Italy, malaria incidence dropped from 400,000 in 1945 to 5 in 1955; and in Ceylon, spraying is now needed only for jungle areas being cleared for farmland.

He continued with a review of malaria control and eradication projects assisted by the World Health Organization, the United Nations Children's Fund, the International Cooperation Administration, and the Public Health Service. He felt that international funds and technical aid are still insufficient.

He stressed the need for more malariologists, particularly for research. Further study of unsolved entomological problems, such as vector resistance to insecticides, must parallel forward planning of the malaria drive. Fundamental malaria research in the United States must be vigorously renewed if the millions of dollars invested in overseas malaria control are to be protected and global eradication of malaria accomplished.

tients with cancer or nontumorous conditions of other sites.

Significant associations found between occupation and gastric cancer involved exposure to iron dust in metal industries and exposure to inorganic dust with free silica (sand) encountered in such occupations as coal miner and pick and shovel operator in road construction. The investigators noted the similarity between these findings and those of an earlier team of investigators who found an excessive liability to gastric cancer among iron, coal, and slate miners.

The association between gastric cancer and exposure to iron dust became stronger with an increase in the probable duration and concentration of exposure, it was stated. Thirteen percent of the patients with stomach cancer and only 1 percent of the controls had been exposed to iron dust for 10 or more years while working as craftsmen, foremen, operatives, or laborers in blast furnaces, steel works, rolling mills, and various metal manufacturing industries, with the duties including at least 3 years of exposure at probable high concentration. Another 18 percent of stomach cancer patients and 8 percent of controls had been exposed to inorganic dust with free silica for 10 or more years.

These associations between gastric cancer and occupation were found to be independent of the factors of smoking, age, race, marital status, population of place of residence, and (probably) socioeconomic status.

It was also observed that 23 percent of all of the stomach cancer patients had been born in Poland, against 6 percent of the control group. The report suggests that the occupational and nativity associations with gastric cancer were independent of each other and that the factors of Polish birth and occupational exposure to iron dust in the same individuals exert an additive effect.

The finding for Polish births, the report continues, was anticipated in a study by earlier investigators of

Chronic Diseases . . .

Suggest Gastric Cancer Tie To Occupation and Nativity

The possibility of etiological links between gastric cancer and occupation and nativity is suggested in a study conducted by the New York State Health Department at Roswell Park Memorial Hospital, Buffalo.

Further testing of the hypotheses is needed, particularly with more

widely representative samples of the disease group and the general population, cautioned Arthur S. Kraus, Dr. Morton L. Levin, and Dr. Paul R. Gerhardt.

In a joint report they described the significant and independent associations between the disease and the two epidemiological variables, revealed in a comparison of the histories of 56 adult males with cancer of the stomach and 677 control pa-

Measures of Morbidity for Cardiovascular Diseases

Although cardiovascular diseases are responsible for only about 5 percent of the attacks of disabling illness, they cause about 19 percent of the days of disability in a white, urban population and account for about 14 percent of days in bed with disabling illness. (PHM chart)

designed to prevent streptococcal infections of the throat.

Physicians are usually quick to initiate antibiotic therapy for even a suspected streptococcal infection, Berliner remarked, but he said they may need laboratory evidence of the infection to justify continuance of treatment for the time required to prevent rheumatic fever. Thus, it is necessary for physicians to have available to them the means of obtaining accurate and inexpensive throat cultures, he declared. He considers the "provision of the means" a challenge of outstanding importance to public health laboratories.

Need for Chronic Disease Programs Reported

The question of whether the future of sound health department practice in the chronic disease field lies in programs of health promotion, disease prevention, treatment, and rehabilitation rather than in services developed according to disease categories, was raised by Dr. Jonas N. Muller, director, depart-

ment of preventive medicine, New York Medical College, and Edward B. Kovar of the United Community Service of Metropolitan Boston.

In a survey of 187 local health departments, the Subcommittee on Chronic Disease and Rehabilitation of the APHA Committee on Administrative Practice found few examples of an integrated chronic disease program although these departments provided many and varied services for the prevention and management of chronic disease and disability, Muller reported.

Almost 60 percent of the surveyed departments consider chronic disease activities a major responsibility of the health department. However, all departments provided many services for the prevention or management of chronic disease or disability, Muller said. Departments which are responsible for general medical care programs, hospitals or institutions, or for both have more services or personnel concerned with chronic disease activities than do departments with no such responsibilities, he stated. A few local health departments reported occupational health programs which give special

attention to chronic diseases and disabilities. Fewer than one-third reported promotion of local implant health service in industry.

Over 60 percent of the departments surveyed had made or had assisted in community surveys of chronic disease problems, needs, services, or facilities; many had made special studies. Almost all departments reported some activity which helps to develop, strengthen, and coordinate community chronic disease services, Muller stated.

He said that community educational activities include public information, distribution of educational materials, exhibits, and speeches at public meetings, illustrated by films and other materials. Some health departments help plan professional school curriculums, staff part of the programs, and, through inservice institutes, take part in the postgraduate education of nurses and occasionally of physicians.

Some health departments provide medical consultation to vocational rehabilitation agencies and welfare authorities. Welfare workers, in turn, provide consultation on economic status and welfare problems of health department patients.

Most health departments offer preventive and diagnostic services; some provide treatment services and a few, rehabilitation services, Muller reported. However, departments providing treatment or rehabilitation services, or both, for children and adults or for adults only are greatly outnumbered by those which provide such services for children only, he said.

Simultaneous screening programs for more than one disease are among the chronic disease activities of some local health departments, and a few departments give group instruction in nutrition or obesity control, Muller stated.

Cooperation between health departments and other community agencies was an important finding of the survey, Muller stated. The services of social workers, nutritionists, health educators, psychiatrists,

conducted in 1953-55 by the recently disbanded Commission on Chronic Illness.

Dean E. Krueger, assigned to the survey by the National Heart Institute of the Public Health Service, reported that household interview data grossly understated the prevalence of chronic diseases.

Clinical examinations are recommended rather than household interviews as a method for studying the prevalence of disease, but it was observed that the amount of disability resulting from chronic disease can be measured as well by interview as by any other method.

The Baltimore interviews yielded only one-fourth of the cases of chronic diseases that were diagnosed by subsequent clinical examination, Krueger said. He added that the completeness of household reporting of disease varied widely among diagnostic groups, that there was no difference in completeness of reporting by severity of the case, that no group was identified for which the reporting of diagnosable chronic conditions in interviews was high, and that proof of the reliability of clinical examinations as a means of measuring the prevalence of chronic disease is needed.

"If clinical examinations are to be used more extensively in studies of the prevalence of chronic disease, criteria for diagnosis should be developed which would emphasize the need for uniformity for research purposes without denying the importance of clinical judgments," he commented.

Reasons for the inadequacy of the interview included lack of knowledge of the condition, use of household rather than individual respondents, deliberate withholding of information, differences in concepts of what constitutes disease and symptoms, limitations of the questions asked, language difficulties, and low mentality of some respondents.

Nonreporting in interviews, Krueger continued, reflected people's deeply ingrained attitudes, their social patterns, and capacities which are not amenable to rapid change.

The Baltimore study provides good evidence that, even though some improvement in content and technique of interviewing can be made, the interview is not likely soon to become a valuable tool in measuring the prevalence of diagnosable chronic diseases, he concluded.

Survey methods used in the study included interviews with a sample of 3,700 households having 11,574 members and clinical examinations of 809 individuals from a subsample of 1,202.

The interview questionnaire included both general questions about sickness, injuries, impairments, and chronic conditions, and extensive checklists of chronic diseases and symptoms of disease. Participants in the subsample had their medical history taken by specialists in internal medicine and received a physical examination plus a battery of medical tests.

Laboratories Can Improve Heart Disease Tests

Within the scope of their present functions, public health laboratories can contribute to control of heart diseases by work on certain laboratory tests and procedures now used in diagnosis and management of these diseases, said Dr. Robert W. Berliner and Dr. William H. Stewart of the National Heart Institute, Public Health Service.

Among the tests and procedures Berliner named were cholesterol determination, prothrombin determination, and methods for obtaining laboratory evidence of streptococcal infection. In most instances, what is needed, according to his analysis, are techniques that will permit mass use of the tests.

Cholesterol and Lipoproteins

Emphasizing the importance of cholesterol determinations, Berliner pointed out that a relationship between elevation of plasma cholesterol concentrations and atherosclerosis has been established although the nature of the relationship is yet to

be determined. Also, he said, it is generally assumed that a regimen that reduces the concentrations will favorably influence the course of the disease. Thus, physicians are using the test more and more as an aid in management of atherosclerosis.

But at present cholesterol determinations on the same blood specimen done by various laboratories are not always in agreement, Berliner observed; hence, the need for a reliable, reproducible test. Development of such a test, he said, might require modification of laboratory procedures, establishment and maintenance of standards, and special training for technicians.

It has been suggested that determination of the amount of the low-density lipoproteins may be of unique value in identifying individuals who are developing atherosclerosis, Berliner continued. The most recent evidence, however, does not support this view, and the expensive apparatus needed for this type of analysis does not appear, at this time, to be warranted.

Other Tests and Procedures

Prothrombin determinations are needed for monitoring prothrombin activity and maintaining coagulability of blood within safe limits when anticoagulants are being used for coronary artery disease. Here again, Berliner indicated, what is needed is a completely reliable, reproducible test that can be done routinely on a large scale.

For differential diagnosis of myocardial infarction, a determination of the serum transaminase levels can be helpful. According to Berliner, transaminase determination is now in the transitional stage between use by basic and clinical laboratories and prospective large-scale use by practicing physicians.

The key to prevention of initial attacks of rheumatic fever is prompt and adequate treatment of infections caused by beta hemolytic streptococci. Also, subsequent attacks of rheumatic fever can be forestalled by a program of medication

DENTAL PLAN

ards, he believes that a substantially higher degree of agreement could be obtained with revised standards and improved methods of orienting the observers.

The hospital record, believed by some to be inadequate for evaluation of medical care, proved a reasonably valid basis for such evaluation in this study, Rosenfeld maintained. Furthermore, he said, deficiencies in the record are in themselves serious since the record is the main line of communication among the many individuals concerned with the hospital patient.

This evaluation method also proved fairly sensitive. According to statistical tests of significance, the difference between the two teaching hospitals barely bordered on significance, but the differences between the teaching hospitals and the community hospitals were highly significant.

Rosenfeld suggested that standards similar to those used in this study may have many applications. Most immediately, he said, they could be used for self-evaluation by medical staffs. The approach offers some promise as a method of comparing performance among institutions.

The objective of the research, according to Rosenfeld, is to develop a method of measuring the quality of medical care that will be suitable for evaluating the effects of community organization of health services. Clinical evaluation of quality is more valid than statistical measures, but it is less precise, he pointed out.

ILWU Welfare Fund Gives Dental Care to Children

Provision of dental care by their union has removed financial and most other deterrents to visits to the dentist by children of longshoremen in the Pacific Coast States, stated Goldie Krantz, secretary of the International Longshoremen's and Warehousemen's Union and the Pa-

cific Maritime Association Welfare Fund, San Francisco.

Beginning in the fall of 1954, pilot dental care programs were set up in a number of Pacific coast ports, with the advice and assistance of the dental profession, Krantz reported. A service plan provided almost complete dental care for a year. Under an indemnification plan, a charge was made for each service. The plans used both closed and open panels of dentists. The open panel included all dentists who were members of the American Dental Association. Both plans excluded orthodontia, cosmetic care, and dental care provided under the union's health program, Krantz said. In Oregon and Washington, bridgework, space maintainers, and topical fluoride treatment also were excluded.

The ILWU-PMA Welfare Fund sponsored both plans in California. In Oregon and Washington, the indemnification plan was sponsored by the fund; service plans were set up by the State dental societies for the fund.

Children were enrolled at local unions in the plan of the parents' choice. The number of children enrolled were:

| Area | Service plan | Indemnification plan |
|------------------------|--------------|----------------------|
| California: | | |
| San Francisco--- | 1,795 | 1,447 |
| Wilmington Harbor----- | 1,843 | 1,108 |
| Oregon----- | 1,666 | 22 |
| Washington----- | 1,949 | 127 |

Costs of Care

Costs for complete dental care were based on results of a sample study of the children. A schedule of fees determined the maximum amount to be paid for a given service. Payments by the union to the service plan were made only for children seen by a dentist rather than for children enrolled, Krantz said. However, the dental profession, the service plan, and the trustees of the welfare fund combined

their efforts to get children to a dentist.

An insurance company acted as agent for the welfare fund in paying the dentists. A deposit premium and an accident premium were paid for each child enrolled plus a percentage of the total premiums to cover the administrative cost of handling claims. Any part of the deposit premium not spent for services at the end of the year was returned to the fund, Krantz stated.

Costs were reviewed and audits certified quarterly. Under the service plan, costs could be renegotiated every 4 months; if needs had been greater than anticipated, the union would either pay a larger deposit premium or would reduce the services contracted for. Under the indemnification plan, it was not necessary to renegotiate the deposit premium during the year. During the first year of the program, \$630,000 was spent by the welfare fund for dental care for children of union members. No decrease in services nor increase in fees was necessary, Krantz said.

Utilization of Services

Based on 12 months' operation, the percentages of utilization of dental services for children from birth through 14 years of age were:

| Area | Service plan | Indemnification plan |
|------------------------|--------------|----------------------|
| California: | | |
| San Francisco--- | 80 | 65 |
| Wilmington Harbor----- | 90 | 59 |
| Small ports----- | ----- | 51 |
| Oregon----- | 76 | 77 |
| Washington----- | 78 | 58 |
| All areas---- | 81 | 62 |

Evaluation and Education

A dental advisory board made up of the dean of a dental school, a public health dental officer, and a member of the committee on dental care of the California Dental Association checked the quality of care furnished under the program. All

psychologists, and physical or occupational therapists who were employed by agencies other than the health department were available to public health nurses. A few local health departments assist community individual care programs through grants and other forms of financial aid and provide equipment,

supplies, and prosthetic devices to other agencies, he said.

In closing, Muller emphasized that efforts to reduce the burden of chronic disease are fully justified but that much information is needed "before the programmatic concept can be applied more generally to developing chronic disease services."

an effort to make the contingency conform to the insurance rather than the insurance serve the contingency. Also, its introduction may hasten more complete coverage and more inclusive benefits in competing plans, he said.

Still unsolved, he said, are many basic questions concerning benefits, rates, and valid controls to prevent unwarranted inflation in health service costs. Costs to the insuring firm can be cut through use of deductible and co-insurance provisions, Pollack said, but their impact is little understood, he added.

Major medical insurance may in time become a catastrophe rider, with or without deductible or co-insurance clauses, in improved basic plans, Pollack believes. In his opinion, it is not now a satisfactory replacement for basic coverage. "The dilemma is that the only alternative plans available to most people also have serious gaps and deficiencies," he concluded.

Medical Care . . .

Major Expense Insurance Raises Basic Issues

By challenging the fundamental concepts on which voluntary health insurance was grounded and by forcing a reappraisal of health insurance objectives, major medical expense insurance has become a critical issue in insurance circles, according to Jerome Pollack, social security consultant, United Automobile Workers.

This significant new form of health insurance, Pollack explained, requires the insured to assume the full cost of a segment of health care, the first \$100, for example, in medical expenses before major expenses begin. Thereafter, it offers reimbursement for most of the cost of a broad spectrum of health services up to a maximum amount, typically, \$5,000 or \$10,000. The broad range of services includes hospital and medical care, private nursing, drugs, and medicines.

The insurance is based on three fundamental premises: If minor expenditures are not insured, more can be spent for protection against major illness. Small claims should wherever possible not be insured because their handling is too expensive for the benefit derived. If the insured is made to share directly in the cost of the services he receives, he will be motivated to purchase care economically.

Opponents of this insurance fear

that it will misdirect and critically inflate the cost of health insurance, that it creates economic pressures which fall unequally on subscribers, that it would emphasize economic rather than medical considerations for developing health services, and that it abandons preventive care as a covered benefit.

The issues raised set reimbursement against direct service; partial against full payment, and standby rainy day coverage for financial emergencies against full coverage of everyday health care.

Pollack described the issues created by this form of insurance, offered judgments supported by new data, and analyzed the basic precepts, with implications of concern not only to organized labor but also to employers and insurance companies.

"Major medical insurance is an attempt to design an appealing arch without a foundation," Pollack stated. "It may prove to have specialized value for people in the upper income categories who have greater need for financial protection against excessive costs than for general prepayment. But persons with lower income will probably continue to need coverage extending far into minor care, even if this amounts to prepayment rather than insurance."

This move to extend coverage is not a panacea for the ills of health insurance, Pollack indicated. He regards it as a bid for preeminence in the health insurance market, and as

Tests Method for Rating Medical Management

By using written standards in analyzing hospital case records, independent observers can achieve reasonable agreement in rating quality of medical care, stated Dr. Leonard S. Rosenfeld, director of the medical care evaluation studies, United Community Services of Metropolitan Boston.

The method was tried in 2 teaching hospitals and 2 community hospitals. Each item of medical care in selected case records was rated "good," "fair," or "poor," on the basis of written standards, and total ratings for each medical specialty were obtained according to prescribed procedures.

Agreement between pairs of observers working independently was better than random although less than perfect, Rosenfeld said. Since many of the differences in ratings were attributable to situations not covered adequately by the stand-

now fully occupied only at peak hours, not for the half or full day. Half of the benches have been removed altogether. Patients no longer complain about long periods of waiting or show other signs of irritation. Physicians and nurses are relieved of pressure. Clinic administration has been simplified by the spreading of the load.

Lee recommends that other hospitals follow suit in reappraising and relocating services. He would avoid fragmentation of care, another defect in outpatient clinic services, by having each patient treated by the same physician, then followed through a continuous system of recorded medical and social information that can be extended, eventually, to communitywide medical care.

Physicians' Views Influence Relationship With Patients

Physicians' tendency to underestimate patients' level of medical knowledge is one reason why physicians give their patients little information about their condition, according to a report by Drs. Lois Pratt, Arthur Seligman, and George Reader of Cornell University Medical College.

In a study of physician-patient interaction in a large metropolitan outpatient clinic, Pratt stated, 81 percent of 89 physicians underestimated the level of medical knowledge of the clinic patients. Such physicians tended to have less discussion with patients than did others.

Analysis of 50 physician-patient relationships showed that most of the patients were told only a few isolated facts about their condition, Pratt observed. The physicians were more likely to avoid completely discussion of the etiology and prognosis than of such immediately practical matters as tests and treatment.

At the same time, the physicians felt that the patients ought to have a considerable fund of medical information, much more in fact than they actually did have, she pointed

out. On a test of 36 routine questions about 10 common diseases, the physicians thought the patients should know the answers to 82 percent, but the patients actually answered correctly only 55 percent.

Also undoubtedly related to the limited discussion between physicians and patients, Pratt said, are the patients' actual low level of medical knowledge and their lack of overt interest in receiving information. The 50 patients studied gave little evidence of conscious, aggressive demand for information from

the physicians although the majority appeared to have an unformulated, latent desire for information.

The dynamics of the situation are something like this, the study has indicated: When a physician believes his patient to be rather poorly informed, he considers the tremendous difficulties of translating his knowledge into language the patient can understand, along with the dangers of frightening the patient, and decides to avoid elaborate explanations. The patient, in turn, reacts dully to this limited information,

Aging Population

In a 1955 population of 165 million, persons aged 65 and over comprise less than 10 percent of the total. Although their numbers increased from 3 million in 1900 to 14 million in 1955, the percentage of those 65 and over rose only from 4.1 in 1900 to 8.6 in 1955. The proportion of the aged appears likely to gain a little in the succeeding decade. (PHM chart)

information on the plan sent to ILWU families and all publicly were agreed upon by the trustees of the fund, the dental societies, and the insurance company.

The dental societies provided speakers for family meetings, sent letters encouraging appointments to each child and letters to dentists clarifying misunderstandings regarding fee schedules. The importance of these contributions to the program cannot be overestimated, Krantz said.

Beginning in July 1956, the dental care program was extended for a full year. In some areas, this meant an extension of 21 months beyond the pilot year, she stated. A quantitative study of the results of the first year of the program is in progress and a report will be available next spring.

Offers Plan for Promoting Family Health Services

The growing significance of industrial health services to the family is intimated in the paper presented by Dr. Harold J. Magnuson, chief of the Occupational Health Program of the Public Health Service, who offers a tip for alerting health departments.

Industrial health services become family centered as families move into industry-centered communities, Magnuson pointed out, where industrial plants are the focal point of social activities and other enterprises requiring cooperative group action.

Even though the contributions of industrial medicine to society are already considerable, their influence is increasing. Some of the factors aiding this development, he said, are the numbers of women in the work force, the mobility and high educational level of the American worker, and the changing character of industrial hazards.

Occupational hazards endangered family health in the past only in isolated instances, Magnuson stated,

observing that the major threat revolved about infectious diseases, such as tuberculosis, which might be brought to the home.

The industry of the future, with its emphasis on automation, electronic and chemical operations, and nuclear energy, will introduce a new dimension in health problems, having potentially far-reaching effects, Magnuson noted. An example, he added, is ionizing radiation which, unless adequately controlled, may affect unborn generations in the families of exposed workers.

The trend in industrial health programs is toward anticipation of disease as well as prevention, he observed. Industrial and commercial establishments, sensitive to the needs of employees, are willing to spend far more on health security than the public health department is able to spend, he continued.

Formerly limited to preemployment examinations, traumatic surgery, and compensation medicine, industrial health programs have stepped up their services, Magnuson indicated, and now offer preplacement examinations, periodic health examinations, and health education and counseling services.

The preplacement examinations are devised to match the worker to the job and to safeguard his health. The periodic examinations prove particularly useful in the detection of nonoccupational disabilities. And the other services are augmented by referrals to appropriate community health and social resources.

Remarking that these gains have been limited to large industries, Magnuson noted that some small establishments have been able to overcome the financial obstacles to similar services only by such devices as banding with other plants. Various plans of such cooperation have evolved over the past 15 years, he said.

He recommended that health departments seize this opportunity to work with industry in developing a "tailor-made plan" that can be adapted to any group of small industries.

By working through industry-centered communities, the health department can add immeasurably to its own resources in the prevention and control of chronic and degenerative disease, he pointed out. The health department, he said, would in effect thus establish numerous branch offices devoted to adult health promotion.

Outpatient Department Tries New System

By coordinating clinic services and instituting regularly scheduled appointments, Boston's Beth Israel Hospital has overcome several defects in outpatient care, according to Dr. Sidney S. Lee, assistant director.

Until 2 years ago, a typical diabetic outpatient at Beth Israel consumed almost 4 hours per clinic visit. Lee reported. The patient was seen by the physician in the diabetic clinic on the first floor, by the nutritionist in the food clinic in the basement, then by the chiropodist on the second floor.

From there he was directed to the social worker on the third floor and out of the hospital by way of the pharmacy on the first floor. His time, often at a financial loss, was thus consumed in waiting and travel.

Relocation of the chiropodist, the nutritionist, and the social worker in the clinic adjacent to the physician and laboratory has reduced the diabetic patient's time in the clinic to 45 minutes, Lee reported.

The new arrangement makes it possible to resolve conflicting opinions on the spot rather than merely to enter them in the patient's record. The number of visits has been reduced for each patient.

The appointment system established 3 years ago at Beth Israel brings 97 percent of all outpatients to the clinic at the time the physician will see them. In most clinics, the patients are seen by the same physician on each visit.

Benches in a given clinic area are

sion of services to organization and quality of medical care, Brindle said. In his opinion, individual health needs can be met only by complete prepayment for a comprehensive range of covered health services, rational organization of medical services, and direct attention to the quality of these services.

When all medical services are included in an insurance plan and are completely prepaid, there will be "no artificial encouragement of medically unnecessary surgery or hospitalization" and medically appropriate services will be used, Brindle stated.

Organization of Medical Care

UAW "is firmly convinced that the problems posed by the increasing complexity of medical science and technology can be met in large part by group practice," Brindle said. Group practice, coupled with complete prepayment for services, will encourage preventive medicine as a matter of good economics as well as good medicine, he asserted.

However, he pointed out, within the group the personal physician must have a central place, for "the personal and confidential relationship between patient and doctor represents the cornerstone of personal health service." But back of the physician must be the specialists, who will work with him to provide complete and balanced health services.

Concerning reimbursement, Brindle said that the method used should relieve the physician of preoccupation with business and fiscal matters and allow him to devote himself to caring for his patients.

Quality of Medical Care

Despite the long history of a "hands-off" policy toward supervision of medical care by insurance plans, such supervision must be developed, not only to control the quality of medical care but to prevent the abuse of medical services when benefits are broadened, Brindle declared. He suggested that a system

of evaluation and professional review by a committee, such as is used by one Canadian plan, might improve the quality of care provided by prepayment programs.

Provision of completely prepaid, comprehensive medical care will be achieved only through "bold and imaginative experimentation," and unions will support such experimentation, Brindle stated. He said that the president of UAW had met recently with a group of interested community leaders in Detroit "to set up a comprehensive medical care program based on group practice by salaried physicians in community hospitals," open not only to UAW members but to everyone in the community.

Management Reviews Medical Care Plans

Industrial management is becoming increasingly interested in non-occupational medical costs and means of paying them, including comprehensive health insurance and other prepayment plans, stated E. S. Willis of the General Electric Company, New York, N. Y.

Medical insurance should provide broad coverage, Willis said, and should pay the major portion of the larger, unpredictable costs of injury or illness, both in and out of hospitals, including specialist care and variable costs such as those due to complications and geographic location. The individual can take care of small bills or bills for preventive medical care, which can be foreseen or planned for, he stated. When small bills occur with such frequency that they become a financial burden, insurance should help in paying them. Medical expenses, although not "happy" expenses, have a definite place in the normal living budget, he emphasized.

Prepayment plans are a form of installment buying, Willis said, and provide basic protection against medical costs. However, they should never supersede direct participation by the individual in payment for medical care. The best individual medical care, Willis pointed out, results from the private practice of medicine, under which the patient has free choice of physician and service and under which he maintains a personal interest in the cost and quality of his medical care.

Epidemiology and Statistics . . .

Controlled Field Trial Of Typhoid Vaccines

Controlled field trials of prophylactics represent one of the most important steps in modern medical progress, asserted Dr. Branko Cvjetanović, of the University of Zagreb School of Public Health, Zagreb, Yugoslavia.

Cvjetanović reported that a trial of typhoid vaccines carried out in Ostijek, Yugoslavia, in the spring of 1954 and 1955, demonstrated that it is possible to prepare an antityphoid vaccine that is effective for man.

This was the first strictly controlled field trial of typhoid vaccines in the history of medicine, he stated. The study was aided by the Public Health Service and the World Health Organization. He stressed the value of a pilot trial and reported that the problems and results of the full-scale field trial were anticipated by the preliminary pilot test.

Typhoid infection in the usual laboratory animals bears no resemblance to typhoid infection in man, and laboratory potency tests cannot be interpreted conclusively because results apparently are more dependent on the tests used and the method

thus strengthening the physician's view and reinforcing his tendency to avoid discussion.

How does the amount of information the physician gives his patient affect the patient's health? This question, Pratt admitted, cannot be answered yet, but, she said, it seems that patients who are given rather thorough explanations participate more effectively in discussion with the physician and are more likely to accept completely his plans for tests and treatment than those who are given little information.

Concept of a Good Physician

Technical competence and skill in handling interpersonal relations received about equal attention in the patients' descriptions of a "good" physician, according to another report of the research at the outpatient clinic. In addition to Pratt and Reader, Margaret Mudd, also at Cornell University Medical College, participated in this report.

About 60 percent of the 50 patients studied mentioned technical competence as an attribute of a good physician, and 58 percent mentioned such factors as kindness, understanding, interest in the patient, sympathy, encouragement, honesty, sincerity, inspires confidence, and "is not in a hurry," Pratt stated. About 24 percent considered both technical competence and interpersonal relations important; about 36 percent mentioned only the former; and about 34 percent mentioned only the latter.

This research, Pratt noted, is designed to determine what constitutes adequate care for patients, to evaluate the adequacy of care offered by the clinic, and to define the role of an outpatient clinic. What patients expect is one element to be considered in establishing standards of care, she said.

Medical Care Goals

Interviews with the 50 patients and observation during their consultations with the physicians provided the following additional information:

The dominant initial goal of two-thirds of the patients was to find out whether they had a serious disease; the rest either wanted a thorough study and a diagnosis or were concerned primarily with treatment.

Almost three-fourths of the patients wanted some kind of treatment or symptomatic relief, and two-thirds of this group specified the kinds of medication or the particular result they wanted. This finding, Pratt observed, demonstrates the pressure physicians are under to give symptomatic treatment.

Most of the patients expressed some interest in obtaining basic information about their problem. However, few made any particular effort to do so by direct questions to the physician or criticized the physicians for not providing it. Apparently, although they have a desire for such information, the clinic patients do not feel that it is the physician's responsibility to provide it, Pratt said.

The patients were notably vague and uncertain about what they thought would be done during their clinic visits, that is, about what types of questions would be asked, whether or not tests would be given, and the like. Also, although most of the patients expected positive results, few hoped for complete cure, and still fewer were really confident of a complete cure. The majority expected symptomatic treatment and reassurance.

Labor Views Medical Care For Industrial Workers

Payments provided by the majority of medical care insurance plans are insufficient to cover the cost of most illnesses, asserted James Brindle, director, security department, United Automobile Workers, Detroit, Mich.

Brindle pointed out that substantial charges are often added to basic indemnity payments for physicians' services and that provisions of income-ceiling service plans often are

not enforced. In many cases, only indemnity insurance is provided, he said, and in some areas which have income ceilings, the ceilings are much too low. UAW has been urging a \$3,000 ceiling for nearly a year and a half but "we are not at all sure that coverage will become available at reasonable cost." In one city where an attempt is being made to develop a \$6,000 ceiling plan, the premium asked is unreasonably high, he said.

Provisions of income-ceiling service plans often are not uniformly enforced, Brindle continued. A UAW survey of charges to workers under the \$3,000 family income-ceiling plans showed that physicians make added charges in as many cases when income is below the ceiling as when it is above the \$3,000 figure.

UAW has been more successful in obtaining full payment of hospital bills than of bills for physicians' services, Brindle said. However, in his opinion, schemes for reimbursing hospitals for services to patients generally do not furnish incentives toward economy and efficiency.

Increased Premiums

The emphasis of most plans on in-hospital care and surgery has led to a substantial amount of hospitalization which is not medically indicated, and this increases prepayment costs, Brindle stated. Indemnity plans keep premiums low by reducing benefits, but service plans steadily increase premiums, he said. Co-insurance, deductible programs, and so-called major medical coverage only shift more of the burden of illness from the group to the individual, he asserted. Brindle emphasized, however, that labor's concern with increased costs of medical care is directed at remediable situations and not at broadening of benefits and justifiable improvements in wage levels, working conditions, and technical facilities.

Areas of Coverage

The focus of labor's demands on health insurance is changing from comprehensive benefits and exten-

Causes of Days of Disability

Annual days disabled per 1,000 persons

Cardiovascular diseases are responsible for the largest number of days of disability annually in the American population. These and nervous and mental diseases rank high because of their long duration. Minor respiratory diseases are a major cause of disability because of frequency. (PHM chart)

The laboratory, in addition to studying the reaction to the various vaccines during the epidemic, analyzed their effect according to the occurrence of AFRI before and after the epidemic and among persons residing in 112 households having one or more virus-positive illnesses. In these households, AFRI attack rates were significantly low in the total and consistently low in each study and age group among persons who received type B vaccines.

Field Trials Are Important In Testing New Vaccines

Field trials are essential in determining the value of new vaccines, stated Dr. W. Charles Cockburn, director of the Epidemiological Research Laboratory, Public Health Laboratory Service, London, England.

Statistical criteria for field studies of vaccines were set up nearly 50

years ago, Cockburn said, although actual trials at that time were unsatisfactory. In the past 20 years, however, these criteria have been used to evaluate pertussis, BCG, poliomyelitis, influenza, and other vaccines.

The early trials of a new vaccine indicate only that the particular lot used is effective under the test conditions, Cockburn pointed out. Then, after the effectiveness of a lot of vaccine has been established, a method of standardizing the antigenic potency of each batch must be devised. However, laboratory standardization of vaccine is difficult, he said, because it has not yet been determined that tests in laboratory animals give a direct measurement of the factor or factors necessary to protect man.

As many batches of vaccine as possible should be tested in the laboratory and in the field, and the laboratory test chosen for standardization should be one which shows good correlation with results of the

field trials, Cockburn emphasized. However, the number of field trials that can be made depends on the number of cases of the disease, and unless the incidence of a disease is high, it is almost impossible to obtain conclusive evidence of correlation between the results of field trials and of laboratory evaluations, he stated.

In closing, Cockburn discussed the health officer's part in vaccine trials. The health officer must be "an unwearying observer that vaccines continue to be of good potency and that they are not provoking unpleasant sequelae," he said. Often the health officer's observations will only point to a problem that will require extensive research for its solution, he stated. "But the important observation is the preliminary one, and in preventive medicine, the health officer is in the best position to make it."

Life Table Applicable To Variety of Studies

The life table has many applications to health and population studies, according to Mortimer Spiegelman, Metropolitan Life Insurance Co., New York City.

Emphasizing its versatility, Spiegelman listed among its uses these: to compare health conditions of communities; to evaluate therapy and as an aid in prognosis; for studies of hospital data; to estimate incidence of certain morbid conditions; and for studies of marriage, population growth, and the labor force.

To introduce his subject, he distinguished between the generation life table, which is a record of a group or cohort covering the period from birth to the loss of the last life, and the current and projected life tables, which represent hypothetical situations.

The current life table is derived from the mortality rates according to age observed during a short calendar period among the many generations then in existence, he explained.

of performance than on the efficacy of the vaccine, Cvjetanović said. Therefore, the issues raised by the differing opinions of laboratories, field workers, and health authorities can be resolved only by a controlled field trial.

Alcohol-killed and alcohol-preserved vaccines and heat-killed, phenol-preserved vaccine were tested on volunteers, using Flexner II phenolized vaccine as a control, Cvjetanović said. Phenolized vaccine proved to be superior to alcoholized vaccine, which suggests that Vi antigen may not play the major role in protection against typhoid fever. The Vi titer in the serums of vaccinated persons was significantly higher following use of alcoholized vaccine. Thus, the vaccines used could be differentiated from each other by serologic tests on vaccinated persons, he stated.

The results of currently used laboratory potency tests of vaccines in animals are not yet comparable with results of potency tests in the field, and further investigations are needed, Cvjetanović stated. Among the questions still to be answered by controlled field trials are the value of acetone-dried and other types of vaccine and the protection conferred by 2 injections of antigen compared with that conferred by 3 injections, he concluded.

Influenza B Vaccine Of Little Value in 1955

In evaluating the effectiveness of influenza vaccines, the Laboratory of Infectious Diseases, National Institute of Allergy and Infectious Diseases, Public Health Service, reported that though type B oil adjuvant vaccine provided definite protection against epidemic disease caused by influenza B virus which occurred in 1955, the amount of protection was slight and perhaps of no practical consequence.

An antigenic shift in type B influenza virus strains, sufficient to overcome immunity to early strains, was suggested as one possible explanation

for the lack of better protection.

As compared with influenza A, the infrequency with which influenza B occurs in epidemic form has made evaluation of vaccines difficult in the past, according to the laboratory.

Participating in the present study, one of a series, were Drs. Robert N. Philip, Joseph A. Bell, Dorland J. Davis, Joseph I. Engler, Gilbert W. Mellin, and Kenneth K. Takemoto. All were members of the laboratory staff during the study.

The laboratory tested the efficacy of the following types A and B monovalent inactivated virus vaccines on separate groups of persons each fall: in 1951 and 1952, two type A (A/PRS, A/FLW/1/50) and two type B (B/Lee, B/Va/1/50) mineral oil adjuvant vaccines; and in 1953 and 1954, two oil adjuvant (A/FLW/1/52, B/Lee) and two aqueous (A/FLW/1/52, B/Lee) vaccines.

Ten thousand forty-six persons

who received only a single dose of vaccine in one or another of the study years were observed for the occurrence of acute febrile respiratory illness (AFRI) during a 7-week outbreak of influenza B in the winter of 1955. Definitive diagnosis of influenza was based on laboratory isolation of influenza virus from AFRI, defined as sudden illness affecting the respiratory tract, lasting 2 or more days, and accompanied by an oral temperature of 99° F. or above.

AFRI attack rates for all vaccination and age groups in the 1955 epidemic were slightly but significantly low among persons who had received type B adjuvant vaccines. Type B aqueous vaccines conferred no protection. One hundred forty-two strains of influenza B were isolated from AFRI occurring during the epidemic. No strains of influenza A had been isolated at any time in 1954 and 1955.

Increasing Life Expectancy

In 1950, the average length of life that could be expected at birth of a white child was about 70 years, up about 40 percent from expectancy in 1900. For a nonwhite child, the length of life expected was 60 years, up 80 percent from 1900. The great gains in length of life have resulted primarily from reduction of infant mortality and childhood diseases. (PHM chart)

the recorded rise in nondisabling chronic conditions may be caused by the patient's telling the interviewer that he still has a condition that he had reported earlier even though it might actually bother him very little, Collis explained.

Some persons in the study population who were not ill at the beginning of the study developed chronic conditions during the study period, some of them disabling and some nondisabling, Collins stated.

Full-time person-years of observation for all individuals, whether sick or not sick, totaled 21,505, Collins reported. For chronic diseases, days of disability totaled 219,857, or 10.2 days per person in the entire observed population. Thirty percent of the total days of disability were spent in bed; 70 percent of the total of 63,696 days in bed on account of chronic disease were spent in the hospital; and 71 percent of the 44,408 days in the hospital were

spent in long-term hospitals for chronic diseases for periods of a year or more or as long as the patient remained under observation in the study.

Days of disability per chronic disabling case averaged 140; days in bed per chronic bed case, 65 days. Days per hospital case in both short-term and long-term hospitals averaged 102 days annually, including cases in institutions for a year or longer.

Summarizing the findings of the study, he reported 1,420 full-time years of observation of patients who had disabling chronic disease at some time during the study period, an annual death rate of 114.8 per 1,000 persons with disabling chronic disease, and a recovery rate of 9.2 per 1,000. Corresponding figures for patients with nondisabling chronic illness were 2,306 full-time years of observation and 3.0 recoveries.

way for "antithrain immunization" prior to each pregnancy, Pasamanick reported.

Lacking preventive techniques for disorders of reproductive casualty, ranging from cerebral palsy to accident proneness, today's best evidence lies in longitudinal studies of children born prematurely or to mothers subjected to complications of parturition, he said. Future research, with control of the many variables, should eventually pin down the relationship of early experience to function in later life, he believes.

Distinguishing between the difficulties in old age that are distinctly vascular phenomena and the disorders loosely called senility, Pasamanick said that, with nutritional improvement, better understanding of psychosocial stress, and expectations for some of the new drugs, deterioration and illness may be prevented or decreased to the point where happy noninstitutional life is possible.

Pasamanick ended his review with a discussion of possibilities in the distant future, predicting facetiously that such terms as emotion, motivation, maturity, anxiety, and thinking will be replaced in scientific terminology by a classification of physiological, chemical, and electrical correlates of behavior.

Mental Health . . .

Foresees Future World Freed of Human Error

The renaissance of medicine and public health brings exciting prospects for alleviating the mental disorders of childhood and old age, according to Dr. Benjamin Pasamanick, director of research, Columbus (Ohio) State Institute of Psychiatry. Ready availability of funds and emergence of scientific method in medical and psychiatric education have stimulated researchers to intensive studies of causation.

New evidence for schizophrenia points to the probability of inborn errors of metabolism within the central nervous system, Pasamanick reported. Similar evidence holds hope for the manic-depressive psychoses, he added. Once the crack is made in the functional psychoses, and he believes it will come within 10 years,

methods of therapy and prevention will follow swiftly, he said. Society is obligated to explore large-scale rehabilitation, he continued, long before thousands of patients return to the community.

In reviewing research progress, largely in his own institute, Pasamanick observed that diseases of hereditary origin no longer appear hopeless. Once the genetic mechanisms are delineated, these disorders will be easy to manage, either by prevention or direct manipulation of chemical constituents, he added.

In mental retardation, there is strong evidence of prenatal factors in organic etiology and sociocultural factors in psychological causes, Pasamanick continued. He described the isoimmunization hypothesis that some women harbor antigens from an infected fetal brain which may damage all future offspring. Research hopes to pave the

Pilot Program Expands Mental Nursing Services

A pilot program allowing public health nurses to offer supportive service to the families of mentally ill patients has been successful in Georgia since January 1953, said Dr. Guy V. Rice, Jr., director, health conservation services, Georgia Department of Public Health.

Followup studies since then have shown that the public health nurse performs this service well, and it is one that gives her a feeling of accomplishment. The family receives her assistance in times of crisis, and she can assist the family also in other areas within her jurisdiction.

The projected life table is computed from projected rates of attrition by death.

Multiple decrement tables and select tables are specializations of the life table, according to Spiegelman.

In the multiple decrement table, he said, the column of the living and,

consequently, other data are split into components on the basis of newly acquired characteristics or of changes in status. For example, in a cohort of females traced from birth, it is possible to distinguish between those who marry and those who remain single.

In the select table, rates of decre-

ment are set down in a two-way classification, Spiegelman explained. One is duration since acquisition of a new characteristic or change in status; the other is usually attained age at time of acquisition or change. For example, rates of remarriage for the widowed may be shown in a select table on the basis of both age at widowhood and duration since the event.

Among examples of life table uses, Spiegelman mentioned analyses by causes of death. The distribution of life table deaths according to specific causes is the first step in computing the changes of ultimate death from such causes, he said. "The desired result is obtained by summing the life table deaths from a specific cause after a stated age and dividing the total by the life table survivors to that age."

For studies of population problems, he mentioned the "net nuptiality" table (attrition by death and by marriage) and the "gross nuptiality" table (attrition by marriage alone), which he said can be used to calculate eventual chances of marriage and the effect of mortality on these chances.

Persons with chronic disease, Baltimore Eastern Health District morbidity study, June 1, 1938-May 31, 1943

² "Recovery" means that the person became free of all chronic diseases.

Baltimore Morbidity Study Reports on Chronic Illness

Rates for disabling and nondisabling chronic illness in Baltimore's Eastern Health District increased 4.9 and 14 percent, respectively, within a 5-year period, according to Dr. Selwyn D. Collins and F. Ruth Phillips, of the Division of Public Health Methods, Public Health Service. Collins, in the W. Thurber Fales Lecture, described the methods used in, and the results of, a morbidity study in the district during the period June 1, 1938-May 31, 1943.

Apparently there are many more persons with a chronic disease or impairment that is not severe enough to interfere with their work than there are persons with a serious chronic disease that causes them to lose time from their regular activities, he stated. However, some of

The mind, while never rigidly differentiated from the body, is more delicate, and, reaching out into the world, it is our most exposed property. It is the most vulnerable part of a person and requires, in a sense, greater care than the body.

Mental hygiene should begin with the life of the normal, or almost normal, man and should attempt to teach him how to live so as to avoid mental illness or to check it in time, the psychiatrist said. It should study the causes of mental trouble in the individual. It should seek to discover the relationship between the personal mind and social life.

Speaking for the benefit of those public health workers and psychiatrists who may still be indifferent to the natural relationship between their areas of endeavor, Liber declared that the hygiene of the mind is destined to participate in all aspects of public hygiene: school hygiene, industrial hygiene, public hygiene of towns, cities, States, and countries, and even international hygiene.

If you are concerned with prenatal care, for example, it is not enough to know something about the pregnant woman's nutrition and the general hygiene of gestation, Liber said. You should also be familiar with the mental state common to women passing through that critical experience: their moods, their needs of sociability or isolation, of tranquility or entertainment.

Anyone interested in infant and child care, he continued, should be thoroughly informed concerning the regular development of intelligence, about the exceptional child, about the particularly gifted or talented, and about the effects of environment on the mental growth of children.

The public health worker in charge of school hygiene would do great injustice to his young clients if he were prepared to deal only with physical health. There is a special school psychology that influences the individual boy and girl, he said.

Liber proceeded to discuss similarly the need for recognition of the interdependence of mind and

body in other health and social areas: child delinquency, crime, married life, industrial hygiene, social work, and health education, for example.

In all the subdivisions of public health work, one cannot help coming in contact with obstacles due to mental states of groups or of individuals, he said. Therefore, the public health worker must be well informed in mental hygiene and, to a certain extent, about mental disease as well, he concluded.

Mental Health Workshops Major Aid to Teachers

Educators are gaining insight into some basic principles of mental health through mental health workshops, according to Dr. Harriett B. Randall, assistant medical director of the Los Angeles City Board of Education.

Such a workshop, she said, was the 1949 pilot mental health workshop in Los Angeles sponsored by the California State Department of Public Health.

In planning the workshop for the Los Angeles city schools, it was possible to invite specialists from various parts of the country to work with the local staff and participants. The staff consisted of psychiatrists, psychologists, and educators.

Seventy-two participants were invited, representing all levels of education and special activities.

Workshop Pattern

Each workshop group had 12 members among whom were an administrator, elementary and secondary teacher, counselor, attendance supervisor, school physician, school nurse, and health coordinator. An educator, a psychologist, and a psychiatrist worked with each group.

The workshop lasted for 2 weeks. During the first period of each day a 1-hour basic lecture was given by a staff member. This lecture represented the topic for the day.

Topics were concerned with hu-

man behavior in infancy, early childhood, adolescence, and adulthood. Special topics covered mental hygiene problems in schools, pupils' emotional problems arising out of physical disabilities, and emotional and interpersonal relationship problems of school personnel.

General and group discussions, playlets, films, and panel discussions interspersed each day's activities.

The workshop was designed to evoke wholesome attitudes and responses in the participants, and brief, meaningful reports on the activities were submitted. These informal reports were incorporated into a mimeographed booklet, along with a statement of the workshop plan and purposes, abstracts of the 10 basic lectures given, and a list of reference materials.

The participants reported that the workshop had given them insight into personal problems and understanding of functional relationships among pupils, teachers, administrators, and school and community agencies. They learned techniques of parent-child counseling and gained perspective through meeting with all levels of school personnel. One of the most important effects was understanding of the principles of mental hygiene and the relationship between emotional growth and development and human behavior.

A followup meeting was held 6 months after the workshop. Many subsequent mental health workshops have followed the pattern of the original workshop.

Invaluable Aid

A survey of reactions to the workshop was conducted in the summer of 1956. Of the original 72 participants, 55 could be located, and they were sent questionnaires. Thirty-six responses were received. The respondents stated that the workshop had been of continuous benefit to them in their relationships with pupils, parents, and administrators. They found the workshop had increased their awareness of mental health. They were able to understand and aid the emotional

The nurse can prepare the family to accept the patient's illness or help the patient take his place in the community when he is released from the hospital. Because the hospital is cooperating with the local health department, it receives valuable information about the patient and his family. Besides assisting the family and the hospital, the health department is a medical source to which other county officials may turn.

Several questions were raised by psychiatric and social work consultants before the program was begun. Was the public health nurse qualified to deal with mentally ill patients? They judged that, since the nurse would be giving the same kind of service that she gives to other patients and families, she would be qualified with proper orientation. Would the nurse be too apprehensive about mental illness to work effectively? It was found that initial fear was allayed after orientation at the State hospital and close supervision by the mental health consultant nurse during the first home visits.

Would the patient and his family resent the public health worker? In a few instances, the public health worker was resented, but most families were grateful and appreciative of the understanding and support given them by someone whom many of them already knew and respected.

Finally, was this a social work job? Much of the work done by the public health nurse could be broadly classified as social work, but the emphasis was on the nurse's professional role, Rice explained.

In order to make such a nursing service plan effective, he added, it is necessary to define objectives clearly, discuss the program fully with all personnel who provide this service to get full acceptance and cooperation, provide adequate orientation in the mental hospital setting, and employ a mental health consultant nurse and mental health worker on the health department staff to provide consultation and assist where necessary.

This supportive service should be an integral part of the local health department program, closely allied with the nursing service, he declared. The nurse should have assistance and advice from a psychiatrist, to whom she can also refer patients. And the hospital and public health and other State agencies should each understand the responsibilities, abilities, and limitations of the other, he concluded.

Baltimore Survey Finds 10 Percent Mentally Ill

Approximately 10 percent of a noninstitutional urban population are at one moment in time mentally ill, according to preliminary data developed from the illness survey in Baltimore by the Commission on Chronic Illness.

This information was reported by Dr. Pasamanick also in collaboration with Dr. Dean W. Roberts, executive director, National Society for Crippled Children and Adults; Dr. Paul V. Lemkau, director, New York City Community Mental Health Board; and Dean E. Krueger, Columbia University School of Public Health.

The estimate may be all too true for the country as a whole, and in any event warrants serious consideration, according to the authors. Baltimore, except for a large non-white population, is similar to other cities in family income and age distribution, they stated, adding that the nonwhite population (27 percent) tends to lower rates.

"We doubt very much that a population having more than this rate of mental illness, in addition to the heavy load of chronic and acute disease found in the Baltimore survey, could function as a society," the report asserted.

Only the psychoses, psychoneuroses, and psychophysiological autonomic and visceral disorders prevailing in a sample of 809 male and female patients of all ages, 86 of whom were diagnosed as mentally

ill, are reported. Full details of the Baltimore survey, including hypothetical leads for further study, will be published by the Commonwealth Fund and the Harvard University Press. Some of the major findings follow:

- The psychoneuroses were 12 times as common as the psychoses, and the psychophysiological disorders were two-thirds as common as the neuroses.

- Male psychoses were twice as frequent as psychoses in women, but women had more psychoneurotic and psychophysiological disorders.

- The psychoses ranged from moderate to severe, or from interference with social and vocational adjustment to inability to function at premorbid levels.

- Impairment in patients with psychoneurotic and psychophysiological disorders either was insignificant or, at most, mild.

- The psychoses rose sharply with age, from no cases under age 15 to few only between ages 15 to 34, but from 5.8 cases per 1,000 population between ages 35 to 64 to the high rate of 27.8 at age 65 and over.

- Under age 15 and over age 64, no psychophysiological disorders were found, but in the young adult group (15 to 34) the number of cases was significantly more than in the middle ages (35 to 64).

Mental Hygiene Related To All Public Health

"The welfare of the mind and of the mental faculties belongs even more to the domain of public hygiene than the well-being of the other human functions because the mind is the principal link between the individual and society," avowed Dr. Ben Zion Liber, emeritus professor of psychiatry, New York Polytechnic Medical School.

The mind, more than the body, he said, must adjust itself to all circumstances of life, must give and take, must make concessions, must find its place among other minds.

bonus, overtime pay, and free medical and hospital care.

Though the average top salary of the sanitarian has been rising more rapidly since 1954 than for any other salary group, the median salary since 1952 has been \$2,000 or more below that of engineers in local health departments and approximately \$750 below the median salary paid to male professional and technical workers in the United States.

Seven percent of the sanitarian positions studied were vacant. Thirty percent of these were available to college graduates with no experience, offering a starting salary of \$4,479. Vacant positions for sanitarians offer higher salaries than filled ones. Among 675 filled positions with the same requirements the median starting salary was \$4,347.

Members of the reporting committee are Walter A. Lyon, chairman, William T. Ballard, Herbert J. Dansmore, Reinhart W. Koch, John W. Lemon, Eric W. Mood, Louis W. Pickles, Jack C. Rogers, and Lester A. Sanger.

Copies of the report may be obtained by writing to Walter A. Lyon, Philadelphia Department of Public Health, Room 630, City Hall Annex, Philadelphia 7, Pa.

New Training Opportunities Stressed in Pennsylvania

The Health Amendments Act passed by Congress in July 1956 "marks a tide that, taken on its full, will lead to signal new achievements" in the training of public health workers, declared Dr. Henry R. O'Brien of the Pennsylvania Department of Health.

Traineeships provided under title I and title II of this act are among the resources used in Pennsylvania to increase professional training of State and local health workers, O'Brien said. He urged all health officers to make definite plans for using the opportunities afforded by

the act, in addition to all other training opportunities.

O'Brien described in detail Pennsylvania's progress in training health personnel since 1948, covering both organization and kinds of training.

Training, an activity found in every division of the health department, is stimulated and coordinated from one place, the division of professional training, he indicated. He considers this pattern the most satisfactory one.

The division of professional training, which O'Brien heads, is responsible for the Pittsburgh field training station. Set up in 1949 by the University of Pittsburgh, the Pittsburgh Department of Health, the State department of health, and the Public Health Service, this unit offers a number of formal and informal courses in various fields of public health.

The division also works closely with the program bureaus and divisions of the State health department, with the State tuberculosis and crippled children's hospitals, with educators in the city and county health departments, and with the universities on matters of education and training for health workers.

In the fall of 1956, the division was paying tuition for 6 workers enrolled full time in schools of public health and for 15 public health nurses studying full time, one from a visiting nurse association, O'Brien stated. In addition, the State department of health is aiding 166 State, county, city, and visiting nurse association nurses who are taking public health courses part time in 9 cities.

A feature of the program to which O'Brien called attention is a register of education and training, kept on 5" x 8" cards, for each of the health department's 900 or more professional and technical employees. Education and general experience before employment by the State and education or inservice training since then are listed. Such a register, he said, aids in planning training for an individual or a group.

Performance Budgeting Believed Oversold

Distinctions between performance reporting, performance budgeting, and program budgeting were delineated by Drs. Leon J. Taubenhau, Brookline (Mass.) Health Department, Robert H. Hamlin, director of the department, and Robert C. Wood, assistant professor of government, Harvard Law School.

Stressing that these practices are not the "be-all, end-all" of administration, but valuable tools nevertheless, the authors indicated that health agencies will find the program budget, used in combination with performance reporting, best suited for program evaluation. The limited size of most health agencies, where not too many operations are routine, plus the intangible nature of health objectives tend to make measurement by the performance budget too difficult, they believe.

In performance reporting, all activities are reported in terms of work accomplished in a specific program. A nursing visit, for example, is reported according to the purpose for which it is performed: tuberculosis, communicable disease, school health followup, or some other typical health service. To be effective, performance reporting must coincide with the program budget, which emphasizes the cost of each program in relation to the total budget. The system must not be oriented to functional bureaus or divisions, they said.

In program budgeting, proposed expenditures are usually presented for salaries, supplies, and equipment. The program budget is merely the traditional line budget presented on a program rather than on a functional basis. Once established, each program budget is developed by the program head and requires little extra effort above that required to produce the annual budget.

Performance Budget

The performance budget has brought confusion to budget circles, especially in health agencies, the

adjustment of their pupils, while increasing their own ability to handle individual classroom and administrative problems.

Of the 22 staff members queried, 11 replied to the questionnaire. They found the workshop an invaluable aid to understanding the problems of educators. Many said that they had learned a lot from the participants. Some said that teachers needed increased knowledge of mental health problems and hoped that educators could participate in further mental health workshop activities.

Reading Disabilities Studied As Clue to Other Conditions

Retardation of reading ability is very often associated with unfavorable environmental conditions or emotional problems, or both, in the child and his family according to preliminary findings reported by the Mental Health Study Center, National Institute of Mental Health, Public Health Service. Drs. Alan D. Miller, Joseph B. Margolin, and Stanley F. Yolles presented the center's findings.

Hoping to develop hypotheses concerning the effect of environment on reading ability and to use these hypotheses to work out a screening device which would be useful in determining the "type of soil in which related mental health problems take root," the authors are studying the reading disabilities among school children in Prince Georges County, Md.

The 2-year survey showed that reading disabilities were $1\frac{1}{2}$ times greater among the children who were patients at the center than among the general school population and that more boys than girls were affected. None of the children included in this sample were mentally deficient.

Starting with the conjecture that a fairly limited disorder, such as reading disability, may be an indication of the presence of other distur-

ances, the initial survey showed that among all the children, ages 7 through 17, examined at the center since 1948, 27.2 percent presented some reading disorder: boys, 36.7 percent, and girls, 23.5 percent.

Children's interests, attitudes, general behavior, the impact of the

family, school, and community on them, and the effect of their reading disabilities on their daily lives are being studied at the center. This report covers one phase of a study of the epidemiology of mental health and illness being conducted at the Mental Health Study Center.

Manpower and Brainpower . . .

Health Departments Lag In Sanitation Salaries

Competition by employers for qualified graduates is reflected in the first of five reports by the Committee on Salaries of the Conference of Municipal Public Health Engineers.

In this competition, health agencies fall by substantial margins to pay the going price for competent personnel in environmental services.

The committee surveyed the salaries of engineers, sanitarians, sanitary inspectors, veterinarians, sanitary directors, and other environmental health personnel in 371 full-time local health departments. In its report is shown the rise in salary levels from 1951 to 1956. Much of the information presented is based on a sample of 35 departments.

According to the report, salaries

have been rising steadily at rates varying from 5 to 13 percent each year, but they do not match those paid in similar professional categories outside health departments.

Present salaries for engineers are well below those paid to other members of the profession. In 1952-54 the median salary was \$1,000 below the median for county and municipal engineers and \$2,400 below the median for all engineers. Under the circumstances, the number of vacant engineering positions in local health departments has tended to increase.

Starting salaries in health agencies for engineers with no experience in 1956 ranged from \$4,250 to \$4,650, but engineering schools predict that their 1957 graduates will expect around \$5,250. In addition to paying higher salaries, private employers tell the young engineer that his interview and moving expenses will be paid, that he will receive an annual

Median maximum salaries of sanitarians and engineers in 371 local health departments by geographic area, 1956

| Geographic area | Sanitarians | Engineers |
|--------------------|-------------|-----------|
| Far west..... | \$5,614 | \$9,000 |
| Central..... | 4,870 | 7,500 |
| New England..... | 4,866 | 6,750 |

| Middle east..... | 4,630 | 7,250 |
| Northwest..... | 4,449 | 7,000 |
| Southeast..... | 3,917 | 6,725 |
| United States..... | 4,776 | 7,140 |

increase of \$500,000 over the 1956 figure, showing the acceptance of the principal of orderly growth.

Reasonable solutions were found for such thorny problems as the relationship between the Pan American Sanitary Bureau and WHO, equitable geographic distribution of seats on the Executive Board and offices in the assembly, the participation of inactive members, and meetings of the Eastern Mediterranean Regional Committee. Scheele noted also that a better understanding of fellow members' problems has evolved in the process of working together.

Assembly discussion of the 1957 program showed a shift from the usual heavy emphasis on communicable diseases to other problems such as heart disease, health aspects of atomic energy, vital statistics, and other WHO services. There was also less stress on professional and technical training. According to Scheele, the discussions reflected smooth cooperation and planning within regional groups. These are all signs of maturity and strength, he said.

Resolutions and Recommendations

The drive for malaria eradication was confirmed as a central objective for the immediate future. At the same time, delegates called for emphasis by WHO on rheumatic, hypertensive, and coronary diseases. Following a challenging debate, he said, the assembly approved WHO's atomic energy program, which includes training of public health personnel; development of standards; and studies on effects of somatic and genetic injury, and on radioactive waste disposal.

The assembly also recommended that the governments of the world maintain close contact with public health authorities at all stages of work on atomic energy projects.

Discussions on radioactive waste pollution of the air, soil, and water produced requests for studies of international streams, and recommendations for cooperative studies by WHO and the Food and Agriculture

Organization to determine the effects of radiation on plants and animals used for food.

One of the highlights of the debate on the International Atomic Energy Agency was the statement by an American delegate urging the new international organization to transfer all its public health activities to WHO in order to benefit from the health agency's 10 years of operating experience.

In preparation for WHO's 10th anniversary celebration in 1958, the 9th assembly called on each member to report on its health situation during 1954-56. Subsequently, he said, all reports will be coordinated into a comprehensive report on world health conditions.

Scheele stated that a resolution accepting Morocco, Sudan, and Tunisia as full members, and the Gold Coast, Nigeria, and Sierra Leone as associate members raised the total number of member states to 88. Attending the 9th assembly were delegates from 73 full member states and 4 associate members.

Technical Discussions

Twenty-one delegations included a nurse, reflecting the theme of the 1956 technical discussions, "Nurses: Their Education and Their Role in Health Programs." He explained that these discussions constitute an unofficial activity accompanying each assembly. Pearl McIver, chief of public health nursing, Public Health Service, directed preparations for the discussions, at the close of which a final report was presented to the assembly.

Directly stemming from these talks was Iran's first conference on nursing, and, in Scheele's opinion, the discussions may well furnish the momentum in many countries for the creation of a nursing service in harmony with the needs, resources, and mores of the individual society.

The World Health Assembly has grown to be the foremost public health meeting in the world, stated Scheele, and during this development it has demonstrated that nations

varying widely in size, race, and culture can work together in harmony, with patience and wisdom.

Proposes New Style Medical Education

Medicine is no ivory-tower profession, insulated from world affairs, said Dr. Gunnar Gundersen, chairman of the Board of Trustees of the American Medical Association. More than ever before, it is one of the vital functions of modern civilization.

The dramatic political and economic events of the last 30 years, a period also of striking advances in technology and communications, have sharpened public interest in world affairs. Scientific gains in medicine have multiplied during the same period, he stated, and through international cooperation, the ultimate in knowledge and techniques are steadily spread over the globe. Individual physicians, medical associations and journals, and international health organizations have contributed to the heartening progress in world disease prevention, nutrition, and medical care.

Spectacular developments in medicine have stimulated mounting public interest in medical care, he said, especially in its socioeconomic aspects. As an expression of that interest he cited the striking growth of voluntary health insurance. Health and medical care are the subjects of more and more social, economic, and political proposals. They are also recognized as important contributors to world peace and stability.

As Gundersen sees it, "the dilemma facing today's physician is this: at the very time that medicine is becoming more difficult to master and keep up with, he must also expand his field of interest and action—both as physician and citizen." Fortunately, there are organizations through which the physician can speak and act.

On the international level, the

authors indicated. The performance budget is basically cost accounting on a service unit basis, designed to test the efficiency with which individuals bring about a group accomplishment. Its focus is on "things to be done or accomplishments to be achieved rather than on things to be bought." The objects of expenditure are always arranged in terms of an end product, expressed as a work or service unit.

The service unit could be a patient examination in a clinic, in which the salaries of physician and nurse, or the cost of supplies and equipment, are prorated according to the number of patients seen. Or it could be a sanitary inspection where the inspector's wages, automobile expenses, and secretarial assistance are grouped together. A dollars-and-cents value is assigned.

Though the purpose of a group of actions in health planning can always be identified, as "X-rays completed," "reports filed," "tons of garbage collected," for example, the authors are convinced that it is not always possible to assign a real value to the service. When applied to tasks requiring professional skill and discretion, a unit cost is often as misleading as it is meaningless, they think. The methods they prefer are direct supervision, reporting, inspection, and a summary presentation of costs.

"We feel that it is more important to have knowledge of the total cost of a program, its percentage of the total budget, and an estimate of its accomplishment in terms of work done, than it is to know the cost of a unit of work as an estimate of efficiency or an illusion of value," they concluded.

Citizens Carry Forward Sanitation Projects

Sanitarians need not work alone in providing clean air, water, food, and shelter for the community; they have in the people an almost untapped resource to call upon, according to Robert E. Mytinger, of the

Paper Cup and Container Institute.

Helping people to do things for themselves is based on two principles, he said. People learn by doing, and the decisions they make usually seem more important to them than decisions that are imposed on them.

Mytinger cited several examples of community action that have supported the sanitarian's efforts.

In Georgia, sanitarians in the Macon-Bibb-Jones County Health Department developed five measures in 1955 with the aid of interested citizens.

First was the passage of a bond issue for the construction of a sewage treatment plant, principally because of the interest and activity of the Macon Chamber of Commerce, the Macon Area Industrial Development Commission, and the National Council for Stream Improvement.

Second, a committee of realtors helped obtain legal support for a five-point housing redevelopment program.

Third was the creation of a county planning and zoning commission.

Fourth, a nursing home committee was formed to help guide sanitation practices in nursing homes.

And finally, through the active assistance of local garden clubs, the

sanitarians saw the beginning of the end of open garbage dumps in the Macon area.

The Tulsa City-County Health Department in Oklahoma found that it paid to get the Tulsa Restaurant Association interested in restaurant sanitation.

Without funds to hire someone to organize a food sanitation training program, the department took the problem to the local restaurant association, where a special committee was appointed to investigate the needs and possible solutions.

The result was a recommendation for a sufficient increase in local licensing fees to permit addition of the new health department staff member. Furthermore, the group endorsed a plan requiring all food workers in Tulsa to take a written examination in connection with the training program. In the first 9 months of operation, 3,600 food handlers qualified.

Mytinger named five categories of potential value to the health worker: official government agencies; voluntary health groups; civic, fraternal, and religious organizations; coordinating agencies, such as a health council or federation of civic or business organizations; and unaffiliated citizens.

World Health . . .

World Health Body Comes of Age

The Ninth World Health Assembly set a new mark in the mature quality of its deliberations and statesmanship, declared Dr. Leonard A. Scheele in an address before the National Citizens Committee for the World Health Organization. Dr. Scheele is president of the Warner-Chilcott Laboratories, and former Surgeon General of the Public Health Service. Among the speakers

following Scheele on the program were Drs. Gunnar Gundersen, D. J. Pletsch, and N. S. Scrimshaw.

Dr. Scheele stated that in contrast with other World Health Assemblies in which a charged atmosphere surrounded some issues and blocked truly decisive action, the 1956 meeting dealt with such problems effectively after calm deliberation.

The regular budget, long subject to pressure for substantial increases, was set at \$10,700,000 for 1957, an

This fact was brought out by Dr. Nevin S. Scrimshaw, regional adviser in nutrition with the Pan American Sanitary Bureau, and director of the Institute of Nutrition of Central America and Panama. He explained that in most Latin American countries deaths are not medically certified; registry is based on information from the family or from family friends.

To determine the true cause of death among children in rural Guatemala, the Institute of Nutrition of Central America and Panama with the assistance of WHO consultants arranged for visits to the families immediately after deaths were reported. INCAP is a cooperative institute organized by the Central American countries and administered by the Pan American Sanitary Bureau, said Scrimshaw.

A study of four representative highland villages showed that two-thirds of all children between the ages of 1 to 5, whose death reports listed diarrhea or parasites, actually died of severe protein malnutrition.

Scrimshaw reported the following steps toward the solution of major nutritional problems, achieved by WHO despite limited personnel and budget.

Endemic Goiter

Endemic goiter was recognized to be a major public health problem in all of Latin America after the visit in 1950 of a WHO consultant who trained workers in a number of countries in endemic goiter diagnostic techniques. Reports since then show that in Peru 36 percent of the men and 64 percent of the women have goiter, and in Panama 47 percent of the adults in certain provinces are affected. Figures for Colombia indicate endemic goiter for 57 percent of the total population; for Guatemala an average of 38 percent; and for El Salvador, Honduras, and Nicaragua nearly 30 percent. In many of these countries cretinism has been reported along with deaf-mutism and feeble-mindedness, conditions prevalent in goitrous areas.

The problem of iodine deficiency in these areas was solved by Dr. Frederick Clements, former chief of WHO's nutrition section who spurred the development of procedures for adding iodine to the crude, moist salt used locally. The iodization process used in the United States was inappropriate because it requires that the salt be refined and dry. With potassium iodate added to salt, the average incidence of goiter fell by 42 percent in 15 weeks in a trial on school children in El Salvador, and 65 percent in 25 weeks in a similar group in Guatemala.

In 1955, two WHO consultants assisted all of the Latin American countries in drawing up regulations for salt iodization and in obtaining the appropriate machinery and supplies. Such measures are expected to eliminate endemic goiter as a public health problem from the countries served, in the next few years.

Kwashiorkor

A tragic aspect of kwashiorkor, a disease most often developing from the lack of good quality protein in the diet of children, is that parents usually mistake its symptoms for those of worm infection. As a result, the little solid food the child receives may be replaced by soft, starchy gruels almost devoid of proteins. Affected children, therefore, often do not reach the hospital, and of those who do, 10 to 30 percent die despite the best of treatment.

Most children who survive the disease do not receive enough protein nourishment for normal growth, as shown in surveys of poor urban and rural areas. The belief that children in underdeveloped countries are small in stature and build because their parents are small is false. Central American children grow satisfactorily until after they are weaned and no longer have mother's milk as a source of protein; it is their almost stationary development during preschool years which accounts for the loss in overall growth. From this great reser-

voir of malnourished preschool children come most cases of kwashiorkor.

Since 1950, when consultants from WHO and FAO collaborated to define the precise nature of kwashiorkor and reported its wide incidence in Africa, a number of studies have been made by consultants of these organizations in Central and South America and by Latin American workers. Stimulated by these studies, research was conducted elsewhere with the result that almost all underdeveloped countries report severe protein deficiency.

It was found that in meeting the need for more protein in underdeveloped areas, increased output of cow's milk and other animal proteins had to be ruled out for agricultural and economic reasons. Fish or vegetable protein of good quality was the practical answer. Pilot efforts in Africa, India, and Central America were sponsored by WHO toward this end. In Central America, a tasty mixture has been devised and has proved to be of such satisfactory quality protein that it is not improved significantly by the addition of milk. It is intended as a food supplement but it is more complete nutritionally than milk itself and less than half the price.

In a common effort to overcome protein malnutrition, WHO is also actively supporting educational efforts against food practices responsible for kwashiorkor; FAO is helping to improve production of animal protein; and UNICEF is distributing and conserving milk as well as supporting the development of vegetable protein combinations.

WHO also provides the stimulus for work on nutritional anemia, pellagra, beriberi, diabetes, and nutritional disorders of the eye; and promotes anthropometric and biochemical measures for the evaluation of nutritional status. A new WHO activity is the study of ischemic or coronary heart disease.

The lower income groups in a number of countries are almost free of coronary heart disease, while in

World Medical Association, composed of the national medical associations in 50 countries, and the World Health Organization maintain close liaison with one another to coordinate the best in world health efforts. These two organizations, Gundersen added, strive for mutual understanding between those in government health work and those in private practice. Their area of closest cooperation is the field of medical education. This, said Gundersen, needs to be specially geared to fit the expanding role of the modern physician.

In 1953, at the First Conference on Medical Education, sponsored by the World Medical Association, speakers emphasized repeatedly the need for better general education of potential physicians. The findings of that conference will be reviewed and correlated at the Second World Conference on Medical Education to be held in 1959 in Chicago.

In addition to medical education, he said, another vital consideration for physicians is the urgency of protecting the ethics, traditions, standards, and freedom of medical practice. Towards this purpose, the WMA adopted an International Code of Medical Ethics and a modified Hippocratic Oath known as the Declaration of Geneva. The association has also set up social security principles to protect the freedom of both the physician and the patient, Gundersen stated.

Malaria Eradication Demands Able Men

Thirteen out of the sixteen countries in the Americas with malaria projects at the beginning of 1955, had converted from control to the technically sounder eradication policy by September 1956, reported Dr. Donald J. Pletsch, chief technical adviser of the WHO Malaria Team in Mexico. Of 10 territories, 8 had converted by the same date.

Reviewing the steps leading to adoption of the global eradication

concept, he stated that the danger of anopheline resistance to insecticides was first pointed out at the 14th Pan American Sanitary Conference at Santiago, Chile, in 1954. He then recalled the gravity of a presentation by Indonesian experts at the Second Asian Malaria Conference in Baguio, Philippines, in 1954, in which they demonstrated the non-susceptibility of *Anopheles sundaiensis* to residual applications of DDT. The 13th World Health Assembly committed WHO to worldwide eradication, and on the recommendation of the UNICEF-WHO Joint Committee on Health Policy, UNICEF gave first priority to malaria eradication.

A number of countries have assumed the temporarily high cost of eradication, said Pletsch. The UNICEF forecast of commitments averages \$8,750,000 for malaria out of a total budget of \$25,835,000 annually for the next 3 years. An allocation of \$1,500,000 for malaria eradication work in 1957 was made by the United States for a special hemisphere account administered by the Pan American Sanitary Bureau.

Plans and financial allotments alone cannot guarantee eradication, he said. The ablest men in this field must be mobilized and wisely used. At this point he presented an estimate prepared by Dr. E. J. Pampana, chief of the Malaria Section of WHO, listing by category the number of specialists needed for every million persons to be protected in any program.

To illustrate how personnel, time, and effort can best be utilized, Pletsch cited experiences from work in Taiwan and Mexico. The guiding principles were adaptation and simplification, he said.

According to the Pampana formula, Taiwan's 5½ million persons in malarious areas required 110 mechanic-drivers. Because the island is too small for extensive use of motor vehicles, however, each sprayer used his own bicycle, and squad equipment was divided among the squad members. Only 9 vehicles were used for the malaria service,

and of these only 5 were normally driven by a mechanic-driver.

The Mexican malaria service has only five professional entomologists for the 16 million people in malarious areas, he said, pointing out that the entomologists in Mexico's 14 zones are actually technicians working under instructions of professional entomologists in Mexico City.

The effectiveness of simplicity and ingenuity when combined with administrative ability was demonstrated by an industrial chemist in charge of a DDT powder plant in Taiwan. To fulfill a request for more than 500 tons of DDT per year, he personally took a Chinese Navy ship to the beaches of Okinawa and brought back a shipload of surplus machinery. In his machine shop, he transformed the material into condensers and jet mills which were used to produce DDT according to the most rigid WHO standards.

In Taiwan, the gravimetric measurement of each sprayer charge of insecticide was facilitated by the general use of the Roman balance or individual beam weighing scale on that island. In Mexico, however, no adequate portable scale or balance was in common use. Measurement was originally made by volume, said Pletsch, until the resulting inaccuracies (up to 20 percent) were pointed out. Efforts by international staff members then produced a simple Roman balance, patterned after the Taiwan model, for weighing 300 grams or 670 grams of insecticides.

Such exchanges of ideas, concluded Pletsch, can overcome graver problems inevitable in the global struggle against malaria.

Links Malnutrition, Child Mortality

Malnutrition is a leading cause of death among children in Latin America, even though mortality statistics for the area show diarrheal diseases to be the principal cause, with malnutrition far down the list.

Milk Sanitation Honor Roll for 1955-56

Seventy-three communities have been added to the Public Health Service milk sanitation "honor roll," and 78 communities on the previous list have been dropped. This revision covers the period from January 1, 1955, to December 31, 1956, and includes a total of 235 cities and 50 counties.

Communities on the "honor roll" have complied substantially with the various items of sanitation contained in the milk ordinance suggested by the U. S. Public Health Service. The State milk sanitation authorities concerned report this compliance to the Public Health Service. The rating of 90 percent or more, which is necessary for inclusion on the list, is computed from the weighted average of the percentages of compliance. Separate lists are compiled for communities in which all market milk sold is pasteurized and for those in which both raw milk and pasteurized milk is sold.

The suggested milk ordinance, on which the milk sanitation ratings are based, is now in effect through

This compilation is from the Division of Sanitary Engineering Services of the Bureau of State Services, Public Health Service. The previous listing, with a summary of rules under which a community is included, was published in Public Health Reports, September 1956, pp. 947-950. The rating method was described in Public Health Reports 53: 1386 (1938). Reprint No. 1970.

voluntary adoption in 436 counties and 1,620 municipalities. The ordinance also serves as the basis for the regulations of 34 States and 2 Territories. In 11 States and the 2 Territories it is in effect statewide.

The ratings do not represent a complete measure of safety, but they do indicate how closely a community's milk supply conforms with the standards for grade A milk as stated

in the suggested ordinance. High-grade pasteurized milk is safer than high-grade raw milk because of the added protection of pasteurization. The second list, therefore, shows the percentage of pasteurized milk sold in a community which also permits the sale of raw milk.

Although semiannual publication of the list is intended to encourage communities operating under the suggested ordinance to attain and maintain a high level of enforcement of its provisions, no comparison is intended with communities operating under other milk ordinances. Some communities might be deserving of inclusion, but they cannot be listed because no arrangements have been made for determination of their ratings by the State milk sanitation authority concerned. In other cases, the ratings which were submitted have lapsed because they were more than 2 years old. Still other communities, some of which may have high-grade milk supplies, have indicated no desire for rating or inclusion on this list.

Communities awarded milk sanitation ratings of 90 percent or more, 1955-56

the upper income groups of most lands and in the United States and western Europe, it is a leading cause of death. These differences were first attributed to poor statistics but it is now apparent that they are real. The comparison of nearly 1,000 aortas from Guatemala and New

Orleans has recently shown that complications of atherosclerosis develop 20 to 30 years of age earlier in the New Orleans group than in Guatemala. These differences parallel those in diet and in way of life; they are not explained by racial factors. A WHO study group met in

Geneva in November 1956 to cover ischemic heart disease, and a second meeting is planned for 1958.

Nutritional deficiencies account for a growing proportion of the total public health problem, as infectious and insect-borne disease control succeeds, Scrimshaw concluded.

Public Health Traineeships for 1957-58

Applications for traineeships in the new public health training program are being accepted for the 1957-58 academic year. Voted by Congress on July 23, 1956, the 3-year program supplies funds to professional health personnel for graduate or specialized training in public health.

More than 330 traineeships have been awarded through the \$1 million appropriation provided for the program's first year. In addition to tuition and fees, stipends cover living expenses for the trainee and legal dependents.

In December 1956, an 11-member advisory committee was set up to assist in planning the program. The members are:

Dr. Franklyn B. Amos, director, office of professional training, New York State Department of Health; Dr. Philip E. Blackerby, Jr., associate general director and director of division of dentistry, W. L. Kellogg Foundation, Battle Creek, Mich.; Robert M. Brown, chief, bureau of environmental hygiene, Maryland State Department of Health; Dr. Rolf Eliassen, professor of sanitary engineering, Massachusetts Institute of Technology.

Miss Roberta E. Foote, director, public health nursing services, The Kansas State Board of Health; Dr. Ruth Freeman, associate professor of public health administration, School of Hygiene and Public Health, Johns Hopkins University; Dr. Hugh Hussey, professor of medicine, Georgetown University School of Medicine, and director of the department of medicine, and physician-in-chief of Georgetown University Hospital.

S. S. Lifson, director of health education, National Tuberculosis Association; Dr. Malcolm H. Merrill, director of public health, California State Department of Health; Miss Marian I. Murphy, professor of public health nursing, University of Minnesota; and Dr. W. L. Treuting, acting chairman, department of tropical medicine and public health, School of Medicine, Tulane University.

Applications for traineeships, which are available from the Division of General Health Services, Bureau of State Services, Public Health Service, should be submitted by April 1, 1957, if possible.

Patients in Nursing Homes and Their Care

NURSING HOMES have emerged to fill a particular set of needs. As they exist today, they respond as much to social needs as to medical needs. The impelling problem is that of accommodating and caring for people who require personal and nursing attention not forthcoming in their own homes or in the homes of relatives. Sometimes this entails a type of care which can be given properly only by trained personnel operating in a special facility such as the nursing home. Sometimes the care required is of a sort which might be possible in one's own home but is not feasible for the particular family or is simply not the desired arrangement. The sheer medical needs for a certain type of care have been reinforced by many physical and social pressures in contemporary life to produce the specialized institution known as the nursing home.

As a relatively new type of facility, the nursing home is not yet clearly conceived and understood. Need for better understanding the role of the nursing home and similar facilities in caring for the chronically ill led the Commission on Chronic Illness and the Public Health Service to join forces in a fact-finding study. To gain the desired insight into the character of nursing homes, the study focused on (a) what type of patients are in existing homes and (b) what type of care these patients receive.

Thirteen States in various parts of the country elected to participate in the survey conducted during 1953 and 1954. These were: California, Colorado, Connecticut, Georgia, Indiana, Maryland, Minnesota, New Mexico, upstate New York, Oklahoma, Rhode Island, Vermont, and Wyoming. Each State performed its own field work and processed and tabulated the data, employing uniform schedules and procedures which were outlined in a manual. Although a technically representative sample was not devised for the study, the consolidated results were found on examination to

Public Health

MONOGRAPH

No. 46

The accompanying summary covers some of the principal findings presented in Public Health Monograph No. 46, published concurrently with this issue of Public Health Reports. The 13-State survey upon which the report is based was a joint project of the Commission on Chronic Illness and the Public Health Service. At the time of the study, the authors of the monograph were associated with the Commission on Chronic Illness and the Division of Hospital and Medical Facilities, Public Health Service. Three of the authors are currently associated with other health and medical care organizations.

Readers wishing the data in full may purchase copies of the monograph from the Superintendent of Documents, Government Printing Office, Washington 25, D. C. A limited number of free copies are available to official agencies and others directly concerned on specific request to the Public Inquiries Branch of the Public Health Service. Copies will be found also in the libraries of professional schools and of major universities and in selected public libraries.

NOTE: In these communities the pasteurized market milk shows a 90 percent or more compliance with the grade A pasteurized milk requirements, and the raw market milk shows a 90 percent or more com-

pliance with the grade A raw milk requirements, of the milk ordinance suggested by the United States Public Health Service.

Note particularly the percentage of the milk pasteurized in the various

communities listed. This percentage is an important factor to consider in estimating the safety of a city's milk supply. All milk should be pasteurized, either commercially or at home, before it is consumed.

Training in Bioassay of Polluted Waters

A training course in the use of aquatic organisms for measuring and interpreting water pollution will be held May 6-10, at the Robert A. Taft Sanitary Engineering Center in Cincinnati, Ohio. It will be followed on May 13 and 14 by a training course in the bioassay of toxic wastes.

The biology of polluted waters course features basic instruction in the nature of various organisms and their response to pollution. The lectures, discussions, and laboratory demonstrations will emphasize new information and new applications and interpretations of data now in use. Professional and technical personnel dealing with aquatic biology are eligible for enrollment.

The course in the bioassay of toxic wastes deals with the effects of the steadily growing quantity, variety, and complexity of wastes on fish and other organisms. Study of these effects often opens the way for evaluation of toxicity so that suitable management practices may be instituted, even if the precise composition of the waste is unknown.

Trainees completing the course will be prepared to set up and run a basic bioassay program.

Applications and further information on both courses may be requested from Harry P. Kramer, Chief of Training Program, Robert A. Taft Sanitary Engineering Center, Public Health Service, Cincinnati 26, Ohio.

One-fourth had been established only within the preceding 2 years. Nonproprietary nursing homes, on the whole, date back longer, as do the chronic disease hospitals.

Public Health Monograph No. 46 analyzes these and other major findings for each of the types of facilities surveyed, that is, proprietary nursing homes, nonproprietary (voluntary and

public) nursing homes, domiciliary care homes, and chronic disease hospitals. Comparisons are drawn wherever possible among the various groups of establishments. The appendix material includes an examination of the representativeness of the States in the sample and detailed tables giving basic data for each type of facility, by State.

Liability of State as Manufacturer and Distributor of Antitoxin

Gielski v. State, 155 N.Y.S. 2d 863 (N.Y. Ct. Cl., 1956) involved a claim against State of New York under the State Court of Claims Act.

Claimant suffered injury to his finger and was hospitalized for tetanus. His physician gave him an intraspinal administration of tetanus antitoxin manufactured and distributed by the division of laboratories and research of the New York State Department of Health. Claimant suffered injury as a result of that treatment. He alleged the intraspinal administration was made in reliance on, and in accordance with, a circular published, printed, and distributed by the State containing instructions and directions for use of the tetanus antitoxin and recommending intraspinal administration. It is alleged that the circular was negligently prepared in that medical specialists in treatment of tetanus did not regard intraspinal administration as safe, and that the circular was prepared and circulated with knowledge and intention that the medical profession would rely on and act on the information therein.

Issue: As a prerequisite to the court's further consideration of the claim under the act, it was necessary that the facts show a legal cause of action.

Holding: The court held the allegations (assumed for this purpose to be true) stated a cause of action, saying:

"The manufacture and distribution of an article dangerous to human life and well being if improperly used, imposes an obligation to advise of the manner in which the article may

be safely used. *Marcus v. Specific Pharmaceuticals, Inc.*, Sup., 82 N.Y.S. 2d 194. Since the obligation to give advice exists it is a necessary corollary that such advice must be given with care. The fact that the instrumentality was distributed only to members of the medical profession for use by them cannot serve to insulate the manufacturer and distributor from liability to the patient as a matter of law. *Wechsler v. Hoffman-Laroche, Inc.*, 198 Misc. 540, 99 N.Y.S. 2d 588."

The court referred to a previous ruling in blood plasma cases where use of plasma collected by the Red Cross and distributed by the New York State Department of Health resulted in death. In the plasma cases it was ruled that where the health department acted merely as a distributing agent of a product for which physicians were generally chargeable with knowledge of appropriate circumstances for use (and it was established in the trials that dangers inherent in use of blood plasma are widely known in the medical profession) the State was not liable to give further information or warning to the physician on the use of the product.

The court said in the *Gielski v. State* case that up to this point in the proceedings no proof as to the knowledge with which the physician is chargeable concerning the use of tetanus antitoxin had been presented, and a physician is chargeable only with such skill and learning ordinarily possessed by physicians in the locality. The court said the circular gave the appearance of reflecting generally accepted medical practice.

present a fairly adequate picture of the Nation's nursing homes.

Information gathered on the patients included personal data, date of admission to the nursing home, diagnoses as available, nature and extent of disability, nursing and personal services received, physician's care, charges, and sources of funds for payment. In addition, information on the length of time the homes had been in operation, their size, and the number and types of staff employed was also obtained. Data on these factors and their interrelationships are presented in detail in the monograph.

The central focus of the study is the proprietary nursing home, which has increased so rapidly in numbers in the last two decades. To perceive in better perspective the role of this relatively new and now quite numerous type of facility, some of the States also surveyed such similar types of long-term care facilities as nonproprietary (voluntary and public) nursing homes, domiciliary care homes, and chronic disease hospitals.

Types of Patients

The findings of the survey reveal that both similarities and differences exist among these categories of institutions, depending upon the emphasis that is given. Basically, it can be said that all of these types of facilities are alike in an important characteristic: They all serve very aged people, predominantly. A large majority of the people in each type of institution are past 65 years of age. With this similarity, significant differences may nevertheless be observed in the age makeup of patients in the four types of facilities studied. Data for five States which surveyed all categories of facilities show that, whereas in proprietary nursing homes as many as 90 percent of the patients are past 65 years of age, in the chronic disease hospitals only about 65 percent are that old.

With respect to the extent of disability among the patients, proprietary nursing homes and chronic disease hospitals serve the groups who are most disabled; voluntary and public nursing homes, those who are, in general, less disabled; and domiciliary care homes, the least disabled group. This gradient is also reflected in the types and extent of services received in the sev-

eral categories of facilities. For example, relative to the other facilities, a higher proportion of the patients in proprietary nursing homes and chronic disease hospitals receive various nursing and personal services.

Information on the length of time spent in the facilities up to the date of the survey revealed that the average patient in a proprietary nursing home had already spent about a year in the present home, the shortest period of residence found among the four types of establishments. Patients in chronic disease hospitals and nonproprietary nursing homes had been in these institutions for somewhat longer periods, and the residents of domiciliary care homes had an average stay to date of more than 2 years.

Such long periods of care naturally impose a severe financial drain on many patients and their families. It is therefore not surprising to find that public welfare funds pay for the care of about half of all patients in proprietary nursing homes. Similarly, large proportions receive such assistance in the other types of homes. Although public assistance does not play quite as large a role among patients in the chronic disease hospitals surveyed, other resources, such as voluntary agencies (including those operating hospitals) and public auspices other than public assistance funds, are financing the care of nearly half of the patients in these hospitals.

Staffing and Age of Homes

Nursing homes without professionally trained nurses are very common. Approximately 60 percent of all proprietary nursing homes have not a single professional nurse on their staff. In a few States where licensure requirements specify high staffing standards, however, nursing homes commonly have at least a supervising registered nurse. Interestingly, voluntary and public nursing homes, although their residents are generally less ill and disabled than the group found in proprietary nursing homes, maintain a higher standard—less than one-fifth of the nonproprietary nursing homes do not employ a professional nurse.

That proprietary nursing homes are still a relatively new phenomenon is demonstrated by the recent origin of many of the existing homes.

technical publications

National Institutes of Health

PHS Publication No. 81. Revised 1956. 25 pages. 25 cents.

The 1956 revised brochure briefly presents the history and programs of the National Institutes of Health, citing significant advances of the individual institutes, divisions, and the Clinical Center.

Recent changes in the structure of NIH are outlined. These include reorganization and expansion to provide a Division of Biologics Standards, the National Institute of Allergy and Infectious Diseases, the Division of Research Services, and the Division of Business Operations. The last two divisions centralize supportive services at NIH.

The pamphlet is designed to reflect the underlying philosophy of the programs conducted by each NIH component. It also illustrates the integration of these programs and the "team approach" characteristic of medical research today.

Four Decades of Action for Children

Children's Bureau Publication No. 358. 90 pages. 35 cents.

Your Children's Bureau

Children's Bureau Publication No. 357. 48 pages; illustrated. 20 cents.

The history of the Children's Bureau and its current program of action for children are contained in two new publications, primarily designed for the wide spectrum of professional workers and lay leaders who want more than a nodding acquaintance with their Government's services for children.

Four Decades of Action for Children shows how the Bureau's responsibilities have grown from its orig-

inal mandate of investigating and reporting on the welfare of children to inclusion of assistance to States, through administration of Federal grants, in expanding and improving their services for children.

Your Children's Bureau describes how the bureau presently works to advance the well-being of all children and especially of disadvantaged children, through its own programs and in collaboration with others in and out of Government.

Procedures for Isolation and Identification of the Gonococcus

PHS Publication No. 499. 1956. 36 pages; illustrated

Originally VD Graphic 84, this 1956 reissue of the manual outlines laboratory techniques for isolation of the gonococcus. It describes materials and media used; how specimens are taken from males and females; preparation of smears; procedure for the isolation of the gonococcus by culture and for performing the fermentation test; and, the identification of *Neisseria gonorrhoeae*. A pictorial diagram shows suggested steps to be followed in this latter technique.

Selected References On Cardiovascular Disease

Annotated bibliography for nurses

PHS Publication No. 472. 1956 52 pages. 25 cents.

Compiled as a time-saving guide for nurses, this annotated bibliography on cardiovascular diseases will also be of use to medical students, nutritionists, health educators, social workers, and others in the health field concerned with heart disease.

References are arranged in sections according to major interests in the field such as rehabilitation, emotional aspects, and patient education. Films and other audiovisual aids are also listed.

The Child Who Is Mentally Retarded

Children's Bureau Folder No. 43. 23 pages; illustrated. 10 cents.

The latest in a series of folders addressed to parents whose children have crippling conditions, "The Child Who Is Mentally Retarded" sets forth some of the home training that parents can give a retarded child. It stresses the fact that retarded children have the same feelings as other children and that most are as sensitive as any other child.

The folder emphasizes, as a springboard for planning, the value of a thorough diagnostic evaluation for a child who appears to be mentally retarded. It also outlines some of the factors which parents would want to consider in deciding either to keep the child at home or place him away from home.

Also described are some of the community agencies and national groups to which parents may turn for help with their individual problems.

This section carries announcements of all new Public Health Service publications and of selected new publications on health topics prepared by other Federal Government agencies.

Publications for which prices are quoted are for sale by the Superintendent of Documents, U. S. Government Printing Office, Washington 25, D. C. Orders should be accompanied by cash, check, or money order and should fully identify the publication. Public Health Service publications which do not carry price quotations, as well as single sample copies of those for which prices are shown, can be obtained without charge from the Public Inquiries Branch, Public Health Service, Washington 25, D. C.

The Public Health Service does not supply publications issued by other agencies.

Scientific evidence indicates that immunization schedules and doses can be varied to fit the conditions of agricultural migrants and other special groups without impairing effectiveness.

Adapting Immunization Programs to Special Groups

By ARTHUR L. TUURI, M.D., HELEN L. JOHNSTON, and DONALD HARTING, M.D.

IMMUNIZATION programs generally follow fixed routines. These fit the convenience of physician and patient and conform to desirable patterns of well-child supervision under ordinary circumstances. For people on the move and for people living in areas remote from health services, conventional patterns may not be applicable. Health workers who attempt to follow them may earn only frustration for their effort.

What flexibility in immunization schedules is permissible under special circumstances? To what extent can time intervals between injections or size of doses be varied without endangering program effectiveness?

This article looks at the problem from the specific point of view of the need for adapting immunization programs to fit the special con-

ditions of agricultural migrants. It reviews recent information regarding the immunization status of the general population, as well as that of migrants. It also summarizes recent evidence of the possibilities of varying immunization procedures to fit special circumstances. Although the article was prepared primarily with the needs of agricultural migrants in mind, the possibilities of varying schedules obviously have wider application if circumstances warrant.

Agricultural migrants in the United States number about three-quarters of a million persons, including both workers and dependents who accompany them. Each year, they move from one area to another to help produce and harvest the Nation's crops. An area may depend on them for its economic existence. Yet local communities may reject them, in part because of the fear that they may be disease carriers.

The mobility of migrant workers in agriculture and their brief convergence on areas that may be far removed from population centers are among the factors that make it difficult for health workers to extend services to these people. Services provided in the usual places and ways and at the usual hours are likely not to reach them.

Temporary arrangements for provision of health services at times and places convenient

Dr. Tuuri, pediatric consultant, Division of General Health Services, Public Health Service, has participated in programs for migrants and Indians, two groups difficult to reach by conventional public health programs. Miss Johnston is staff adviser in the field of rural health, and Dr. Harting is chief of the Program Development Branch, Division of General Health Services.

Important contributions to this paper, especially concerning diphtheria, were made by Dr. Alexander Langmuir and Dr. Helen Moore, Communicable Disease Center, Public Health Service, Atlanta.

Public Health Reports, published since 1878 under authority of an act of Congress of April 29 of that year, is issued monthly by the Public Health Service pursuant to the following authority of law: United States Code, title 42, sections 241, 245, 247; title 44, section 220. Use of funds for printing this publication approved by the Director of the Bureau of the Budget, September 17, 1954.

U. S. DEPARTMENT OF HEALTH, EDUCATION, AND WELFARE
MARION B. FOLSOM, *Secretary*

PUBLIC HEALTH SERVICE
LEROY E. BURNET, *Surgeon General*

sibility that they may contract and carry disease from one place to another are matters of concern.

Two outbreaks of diphtheria were reported among people living in migrant labor housing during the first 6 months of 1956 (2). During 1955, an outbreak of chickenpox among migrant workers in Lee County, Ill., led to an investigation by the Illinois Department of Public Health. A report from the county states: "A minority of the entire personnel showed evidence of previous smallpox vaccination, and only a few of the children had ever received immunization against diphtheria, pertussis, or tetanus" (3).

A Colorado study based on interviews of 260 migrant families, including 1,153 adults and children, during 1950 indicates that only 42 percent had had smallpox vaccination and probably only 1 out of 5 or fewer were immunized against diphtheria, whooping cough, or tetanus (4). Informal reports from several Colorado nurses who are working with agricultural migrants are in accord with these findings. Health workers in other areas have made similar reports.

In some of the labor camps and fringe areas of population centers where agricultural migrants live for brief periods, living conditions

are primitive. Occasional outbreaks of typhoid fever occur. This situation is believed to warrant consideration of immunization against typhoid fever for agricultural migrants even though this is not advocated for the general population under ordinary conditions.

State Immunization Policies

The Committee on the Control of Infectious Diseases of the American Academy of Pediatrics recommends that combined immunizations against diphtheria, pertussis, and tetanus be given "at intervals of not less than 1 month and preferably not more than 3 months" (5). The States and Territories are using this standard to an increasing extent in setting policies for their immunization programs. States continue to vary, however, in their policies and in the standards to which they refer.

This State-to-State variation in itself suggests that flexibility in immunization programs is possible. However, the policies in each State, whether or not set by law, have frequently been translated into long-standing practices that are strictly adhered to in immunization programs whether the programs are carried out in the offices of private physicians or in public clinics.

In comparing State immunization policies, Eliot noted that 22 States and 1 Territory set the maximum permissible time interval between injections in the primary DPT series at 1 month. No flexibility is permitted in this time interval. Two States and two Territories permit an interval of 3 months between primary injections, and 3 States permit a 4-month interval. Eight States and one Territory, on the other hand, permit an interval of 6 months between injections without requiring that the series be restarted (6).

Effect of Lengthened Time Interval

Opinions differ as to the levels of antitoxin in the blood serum necessary to confer immunity against diphtheria and tetanus. The evidence available, however, points to as high or higher levels of antibody response when the interval between doses is prolonged as when the interval is the length usually recommended for primary immunization. Jones pointed out

to both the workers and their employers may sometimes be possible. Immunization services, however, differ from most others in that there is a general belief that fixed time schedules must be followed if immunization is to be effective. Many health workers hesitate to initiate a series of primary injections unless they are sure that they can complete the series in accordance with the customary time schedule.

The frequently severe reactions among adults to the usual doses of antigens also deter immunization programs among migrants. The reactions in adults may cause great discomfort and even loss of time from work at a period which is crucial for both workers and employers. Such problems, of course, are not peculiar to the agricultural migrant population.

Immunization Status

The available information concerning the immunization status of the population is chiefly in terms of the continued occurrence of diseases for which effective control techniques have long been known. Diphtheria, for example, has long been subject to control by immunization. Yet data compiled by the Communicable Disease Center, Public Health Service, show that more than 2,000 cases of diphtheria occur each year over the Nation as a whole.

Special studies seem to indicate a shift in the importance of diphtheria from the younger to the older age groups. A long-term study of age-specific mortality rates in Massachusetts shows that diphtheria mortality rates among children under 10 years of age have declined throughout the period 1921-53. In other age groups, however, the long-term decline was interrupted in the early 1940's, as shown in figure 1 (1). More than half the cases of diphtheria in California during the period 1950-54 were among persons over 19 years of age, according to Communicable Disease Center data. In the southern States, the shift in the importance of diphtheria from younger to older age groups is much less prominent, although this region, too, shows some increase in the proportion of cases in age groups over 19 years.

Some of the southern States, including Texas, have reported more cases and a greater number of diphtheria outbreaks than other parts of the

SOURCE: Reference 1.

country in recent years. Data for these States show that diphtheria among the nonwhite population is on the increase. These same States supply a large segment of the labor force that annually moves northward from one crop harvest to another.

To a somewhat lesser extent than diphtheria, tetanus continues to be an important problem. The proportion of cases among children and young adults has decreased in recent years. These are the groups most extensively reached through immunization programs for young children and for military personnel. The proportion of cases among older adults, however, has been gradually increasing. According to a Massachusetts study in 1954, more than one-half of the persons over 20 years of age had antibody levels of less than 0.01 units of antitoxin. Women had significantly lower antibody levels than men, as shown in figure 2 (1).

How much the situation among agricultural migrants may deviate from that in the general population is not known. In the opinion of public health workers and others familiar with the situation, however, migrants' lack of protection through immunization and the pos-

SOURCE: Reference 8.

the use of triple antigens with injections from 6 to 12 months apart are at least as good as the levels obtained when the antigens are given at intervals of from 1 to 4 weeks.

There is also evidence that when the time interval between primary injections is increased, a higher immediate antibody level is produced by a stimulating, or secondary, injection given 3 months to 7 years later (8, 9).

In infants studied, there was no relationship between a poor initial response and the recall response obtained years later with diphtheria and tetanus toxoids. It appears that adequate recall response can be expected in most cases in spite of poor initial response (10). The majority of adults will show protective antibody levels within 6 days after a recall dose of tetanus toxoid as long as 10 years after primary immunization (1, 12, 13).

Taken together, these data suggest that the usual telescoping of injection schedules has value chiefly for the convenience of physicians and patients, for emergency situations (1), or for producing immunity in infants as rapidly as feasible at a time when the hazards are likely to be the greatest for the infant. Many immunologists believe that ineffective immuniza-

tion is more likely to result from relatively short intervals between doses than from long intervals.

Methods of Reducing Untoward Reactions

Three methods of decreasing severe reactions to diphtheria toxoid among adults are to immunize only susceptibles as determined by the Schick test, to use purified toxoids, or to decrease the dose of toxoid. The first, of course, might not be feasible for a seasonal farm worker since he might be on his way to another work location by the time the results of the test were known. The second decreases the incidence of reactions only in age groups under 30 years (14).

On the basis of present evidence, the most effective means of decreasing untoward reactions in diphtheria immunization is by decreasing the dose of toxoid. Small doses of diphtheria toxoid (in the range of 1 Lf per dose) can be used to immunize adults successfully without regard to selection of Schick positive individuals (11). Only occasional reactions are encountered with 1-Lf doses (table 1).

Table 1. Reactions to 1-Lf diphtheria toxoid

| Degree of reaction | Number of subjects | | | |
|--------------------|--------------------|------------------|------------------|------------------|
| | Local reaction | | General reaction | |
| | FTT ¹ | APT ² | FTT ¹ | APT ² |
| None..... | 5 | 39 | 42 | 71 |
| Mild..... | 27 | 31 | 8 | 2 |
| Moderate..... | 14 | 4 | 5 | 0 |
| Severe..... | 10 | 1 | 1 | 2 |
| Total..... | 56 | 75 | ----- | ----- |

¹ FTT=fluid toxoid, in tetanus toxoid.

² APT=AIPO₄—adsorbed toxoid.

SOURCE: Reference 11.

In studies conducted by the Commission on Immunization of the Armed Forces Epidemiological Board with doses of 1 Lf (in 0.5 cc.), less than 5 percent of the patients had systemic reactions. (The vaccine usually used in immunizing children contains 20-25 Lf/cc.) Although there has been some question as to the

that by increasing the interval between injections for immunization against diphtheria, a higher antibody response is seen (7). Similar findings of higher antibody levels with longer intervals between tetanus immunizations have been reported by Bigler and Werner (8), Bigler (9), and Deamer and associates (10).

In a controlled study in which an interval of 6 months or more between first and second primary diphtheria and tetanus immunizations was compared with a 2-month interval (figs. 3 and 4), Bigler and Werner found that the immediate antibody response averaged 4 times higher for the longer interval than for the shorter (8).

In a group of children receiving primary tetanus injections at intervals of from 6 to 51 months, Bigler noted that 6 months after the final injection the titers were in the same range as those present in children receiving primary

injections at intervals of from 1 to 3 months (9). Deamer and his co-workers confirmed the findings of a higher tetanus antitoxin response in infants when the interval between injections was lengthened (10).

Ipsen noted a satisfactory antibody response in the tetanus antitoxin titer in previously unimmunized adult men who were given small doses of toxoid (5 Lf) at an interval of 23 weeks between the first and second primary injections (1). Edsall and his associates demonstrated diphtheria antibody titers greater than 0.03 units per milliliter in 250 of 252 patients given 1-Lf doses of adsorbed diphtheria toxoid with a 5-month interval between the second and third doses (11).

According to Dr. J. H. Lapin, attending pediatrician, Bronx Hospital, New York City, other investigators report that antibody levels for diphtheria, tetanus, and pertussis following

Figure 3. Comparison of 6-month interval and 2-month interval between first and second injections of combined alum precipitated diphtheria and tetanus toxoid as to titers of diphtheria antitoxin.

SOURCE: Reference 8.

summarizes evidence that the use of small doses of antigens is effective in minimizing untoward reactions; at the same time, these small doses produce adequate antibody response. The small doses also lend themselves to use in a combined vaccine, thus decreasing the number of injections required.

If the usual patterns followed in immunization programs can be conveniently fitted to any group, including agricultural migrants, no change in these patterns is suggested. However, permissible variations, such as those reviewed in this paper, need to be considered in order to tailor programs to groups which are difficult to reach by conventional means.

effectiveness of these small doses as a primary antigenic stimulus, they are known to be effective as a recall dose for maintaining a satisfactory immunity level (1, 11, 15). Results obtained with 1-Lf doses in two studies are given in table 2 and figure 5.

In immunization against typhoid fever, systemic reactions can be reduced considerably and protective levels of antibodies can be achieved by intracutaneous administration of typhoid-paratyphoid vaccine (16-18).

Combined Antigens

For the past 5 years, the Canadian Armed Forces have used a vaccine containing typhoid, paratyphoid, tetanus (8 Lf), and diphtheria (4

Lf) antigens. The results of studies of this vaccine compare favorably with data relating to children who have received 3 doses of fluid toxoid (19). The vaccine proved effective both as a primary stimulus and as a secondary stimulus and provided antibody levels as high as 3 doses of plain toxoid.

Use of such a combined vaccine would greatly simplify immunization procedures among adults in the agricultural migrant population since it would decrease the number of injections by about one-third. In addition, as indicated by the preceding information concerning lengthened time interval, the interval between injections may be increased far beyond the conventional limits with satisfactory results.

Summary

Agricultural migrants and other mobile or isolated population groups have long frustrated health workers' efforts to fit them into conventional immunization programs. All too frequently, the belief that any deviation from standard procedures would preclude an adequate immune response has led health workers to avoid attempting to initiate immunization procedures when conditions would not permit following the usual patterns.

This paper reviews evidence which refutes the frequently held view that if the doses of antigens cannot be given at the usual time intervals, or if one injection is omitted, the entire series of primary injections must be restarted and completed in the usual sequence in order to attain effective immunization levels. It also

privations, or until the advantages of death seem to outweigh the burdens of life. Life is, indeed, precious to the old.

- To get more rest, or, perhaps, to get release from the necessity of wearisome exertion at humdrum tasks and to get protection from too great exposure to physical hazards—opportunities, in other words, to safeguard and preserve waning physical energies. Old people have to learn to hoard their energies.

- To remain active participants in group affairs in either operational or supervisory roles, any participation being preferable to idleness and indifference. "Something to do, and nothing to be done," is perhaps the main idea.

- To safeguard or even strengthen any prerogatives acquired such as skills, possessions, rights, authority, and prestige. The aged want to hold on to whatever they have. Seniority rights are zealously guarded.

- Finally, to withdraw from life, when necessity requires it, as honorably and comfortably as possible and with maximal prospects for an attractive hereafter.

These five interests—longer life, rest, participation, prerogatives, an easy and honorable release—probably can be subsumed under the two words "influence" and "security" if they are used with broad connotations.

We have observed impressive uniformity in these interests regardless of time and place.

But the ways of adjusting to, and the appraisals of, aging show very wide variations. In short, what we oldsters want is simple and clear, but how to get it is complex. It would seem, indeed, that every conceivable adjustment has been tried out by people somewhere in their attempts to enrich and round off the last years of life.

In worldwide perspective, old age may be said to begin relatively early or late in life and to last a long or short time. Its coming may be resented and discounted or welcomed and treasured. Some people actually try to "hurry up and get there," while others postpone it to ridiculous degrees.

When it does come it may be regarded as an idle and useless period or as an active and fruitful one. It may bring promotions in position and homage with the years or demotions and degradations. It may drag itself out in dull,

t tedious boredom or go by quickly and with zest.

The people in one society may look forward to a full and ripe old age; in another, next to none at all; and in still another, to long and empty spans of timepassing. Some may beg to be put away honorably, and others may long to live on even in their misery. Thus, from place to place and from time to time, aging may be viewed as a curse on the one hand or as a challenge on the other.

Here is a generalization, though, that seems to hold universally: Every human being has had either to die or grow older and, in this dilemma, the social and cultural factors have been extremely important.

Very significant aspects of the social and cultural factors in aging are the inculcated patterns of interpersonal privileges and responsibilities that require or inspire the young and the sly to respect and to provide for the old and the feeble.

All the evidence indicates that these patterns of behavior are not inborn; they are built into the culture. It is almost a maxim that man is the only animal that can be made, willy-nilly, to take care of his grandfather.

Nature in the raw has never been very kind to old age anywhere and in any species. Security for old age is distinctly a human-culture achievement. The taming and the use of fire is a simple example of how man's material culture can serve and comfort the aged. When fire was finally brought under control, used as a defense against climate and wild animals, applied to the manufacture of implements and the preparation of food, and made a stabilizing factor in family life, with its warm hearth and cozy corner, a new day had dawned for the elders. Indeed, the advantages of fire were soon so closely associated with the frailties of age that when the necessity arose to abandon an old and enfeebled relative it became a popular rite and last favor to leave him with a supply of food, a flame, and some fuel.

There are equally important examples of security for the aged in the development of social relations, such as rules obligating the young to respect, heed, and provide for the old in many and varied forms. Property rights are an outstanding example. But whether and how well any of this has been done depends greatly upon

AN ANTHROPOLOGIST

Views Old Age

By LEO W. SIMMONS, Ph.D.

OLD AGE may be viewed either as a problem or a challenge, and both socially and personally. I submit two quotations, one stressing the problem side and the other signifying the challenge.

Cato the Elder is reported to have said: "For my part, I prefer to be an old man for a somewhat shorter time, than to be an old man before my time." He saw the problem side.

One Joseph Choate concludes that people are really happiest in their seventies and eighties, so his advice is, "Hurry up and get there." He sees the challenge.

However we look at it, we are confronted with the plain fact of a spectacular increase of old people all around us. We can see these old people in the present or we can study them in the past.

My own interests have led me more toward the cross-cultural and worldwide views on aging than to the specifics of our present times.

It has been very helpful to look for the uniformities and the common elements that underlie the experience of old age in different times and places. One way to state this issue is to

ask: What is new and different, really, and what is old and common to all mankind in this matter of aging? Answers to this question give us background, points of orientation, and they may also highlight the current issues of our own age.

Among many peoples in primitive and historical settings, I have looked for two things:

- The persistent or recurring interests of aging persons. What are their needs or what do they want, almost everywhere?
- The solutions that different societies have made to the problems of aging. What have different peoples done about the needs of aging? What solutions are most fundamental and widespread?

It turns out, as I see it, that the basic interests of aging persons appear to be more uniform than the solutions or the appraisals of these solutions.

What We Want

A careful survey over a long period of time of 71 different peoples, distributed worldwide, has disclosed recurring interests of aging persons that can be summed up pretty well in a five-fold way:

- To live as long as possible, or at least until life's satisfactions no longer compensate for its

Dr. Simmons, professor of sociology at Yale University, is noted for his studies in social anthropology and medical sociology. Among his publications is "The Role of the Aged in Primitive Society."

it. That is a long story that has to be skipped here.

The big point for us is that in primitive societies and, indeed in all societies until modern civilization, this over-age period has not been very significant. Few persons reached this stage; they didn't last long in it. Some were dispatched with varying degrees of dignity and prestige.

The helpless and hopeless period takes on paramount importance, however, in our own civilized times. We are so successful in keeping very old people alive that we don't know what to do with them. Imagine the magnified possibilities of living parts of aging bodies scattered around here and there! Add to this the recognized fact that the useless period is largely socially and culturally determined and that it may be moved up or put off in years. The problem thus becomes unpredictable and staggering.

The social fates are most unfortunate, of course, when so many old people are made to feel useless relatively early in life and to find the twilight years empty, lonely, and long lasting. More and more of life with less and less in it is not a happy prospect. Thus can civilization create more problems for aging than it has yet solved. Death is really the only ultimate solution. Whether life can be good to the last drop or not really depends on when and how we drop.

Our fourth lesson is that there is a pattern of participation for the aged that becomes relatively fixed in stable societies but suffers disruption with rapid social change.

We know that stable societies provide a structured framework for participation, with status and roles that are defined, sex typed, aptitude rated, and age graded. If the pattern stays fixed over many generations, the aging get a lifetime to fit in and entrench themselves.

Here is one way to express the general principle: In the long and steady strides of the social order, the aging get themselves fixed and favored in positions, power, and performance. They have what we call seniority rights. But

when social conditions become unstable and the rate of change reaches a galloping pace, the aged are riding for an early fall and the more youthful associates take their seats in the saddles.

The general pattern for the adjustment of the aged in society fits into five more or less social structures of human groups: (a) the economic order, (b) the family system, (c) the political system, (d) the religiomagical institutions, and (e) the socioeducational systems. It is a long and interesting story to document the changes imposed upon the aged in making adjustments to shifts in these five systems. In general, it can be said that change is the crux of the problem of aging as well as its challenge.

The fifth and last lesson is that the modern challenge is to explore and experiment anew with aging.

We have more aged persons than the world has ever known: 14 million in the United States 65 years old or more and 26 million anticipated by A. D. 2000. And these people are already born! Old age is beginning earlier, with more untapped and unused resources than in earlier times. The old tried and tested patterns of participation and security have been disrupted, and they are passing away.

Perhaps the most important lesson that can come out of the past is that the basic qualities of successful aging rest, after all, upon the capacities and opportunities of individuals to fit well into the social framework of their own times, and in ways that insure prolonged influence and security.

It may well be that there are no genuine substitutes for suitable adaptations and true contributions of ripe age. Certainly the challenge is to rediscover them for the modern world.

We are now accustomed to hearing much about the problems and little about the opportunities of aging, almost as if aging were a curse—and after all our efforts to attain it! It should be kept in mind that the prospect of so many of us reaching old age is in itself a most remarkable achievement, entirely unknown to earlier times. Let us not forget, therefore, that

the existing culture of the time and place and the organization of society itself.

It is noteworthy that in some societies such solicitude for the aged has seemed to fall squarely in line with the self-interest of the young. In such cases the solicitous youth could have said of his aid to his elders, truthfully and without pathos, "Grandfather, this helps (not hurts) me more than it does you." In other societies youth does not see such a connection. Why? The answer lies in the culture and the social organization.

Here is an important general principle to consider: Whenever society has provided a mutually supportive relationship between its youth and its elders, old-age security has had its firmest foundation. In contrast, the severest hazard of the aged and the infirm has been to find themselves cut off from the young and the able bodied upon whom they have had to rely. One could speculate that the time may come when youth can manage without the aged; but whatever widens the gap between the two will, more than likely, be at the expense of the latter, especially in the extremities of their dotage. There is no substitute for the ties that bind youth and age in common interests.

Five Lessons in Aging

From here on I will list a few simple lessons that I have learned about aging, five lessons in fact.

First, aging has become a complex and challenging proposition to face personally.

Let me illustrate this lesson with the mention of two common mistakes. The first mistake is to try to compare and to choose between old age and youth. We cannot do that. The choice, really, is between aging and dying. We've had our youth, some of us at any rate. Now, for us, it is age or else. The second mistake is to regard aging primarily as a time of resting, however much we think we like resting. "Old age for rest" is only a half truth at best. The efforts and the strategy of life had better go on, refined and intensified to be sure. Aging successfully is somewhat like riding a bicycle—to stop is to go down.

My second lesson in broad perspective is that aging can be good or bad, and when it is good

it generally is more of an achievement than a gift.

A person, of course, must get to be old before he can make it good, and most human beings have never been able to get there. The farther back we go in human society the earlier people became "old," but fewer and fewer old people are to be found back there.

There was a great surprise to me in my studies of aging. Societies solved the problems of a successful old age for a few long before they could assure any old age at all for the many. For a long time, in a few spots on earth, one has been able to say truthfully with Joseph Choate, the happiest years of life are in old age. So let's hurry up and get there. There are primitive peoples who frankly regard old age as the best part of life, and they try early to appear, and to be regarded as, older than they are.

Now we suspect that civilization has made the aging period for most of us something less than the best of life. All this ties in with the social determinants of when we become old, on what terms, and how long we are permitted to last. A secret of success for most people facing old age is to find for themselves places in society in which they can age with participation and fulfillment, and to keep on participating tactfully and strategically up to as near the end as possible. Aging must be gamey to the end to be very good.

The third lesson out of our broad background studies is that a stage is reached in aging everywhere in which social assessments of the condition are uniformly dismal.

Among all peoples a point is reached in aging at which any further usefulness appears to be over and the incumbent is regarded as a living liability. Senility may be a suitable label for this. Other terms among primitive peoples are the "over-aged," the "useless stage," the "sleeping period," the "age-grade of the dying," and the "already dead." Then, without actual death, the prospects are gloomy. There is no question about this generalized social decision; the differences lie in the point at which it is reached. All societies differentiate between old age and this final pathetic plight. Some do something positive about it. Others wait for nature to do it or perhaps assist nature in doing

This outline of the nature, basis, and method of eight interrelated surveys calls attention to the wealth of published material applicable to an evaluation of oral health needs and resources.

Planning Surveys To Assess a State's Oral Health Status

By DAVID F. STRIFFLER, D.D.S., M.P.H.

THE PUBLIC HEALTH dentist proceeds to assess the oral health status of his "patient," the State and its people, along much the same lines as does the dentist in private practice (1). First, he listens to his patient's chief complaint, and then he sizes up the patient and questions him. Next, he makes a clinical examination, using all the necessary diagnostic instruments. Finally, he records his findings so that he can analyze them and arrive at a diagnosis.

The survey, whether formal or informal, is the method the public health dentist uses to make his assessment. Surveys can serve many specific purposes. They can provide an accurate basis for identifying the real, as opposed to the apparent, oral health problems (2); guide the assignment of priorities in program planning and budgeting (3); provide baseline data for future program evaluation (4-8); supply data needed in anticipation of new pro-

grams, such as prepayment dental care plans (9-11); "determine the epidemiological characteristics of a dental disease . . . establishing the manner in which the disease is manifested in population groups . . ." (7).

We shall outline specific objectives and practicable procedures for eight types of interrelated surveys, all directed toward the assessment of the oral health status of a State and its people. We shall give attention also to special problems, for, as in the private dental office, emergencies frequently intrude to upset the best of planning. Finally, we shall consider plans for analyzing and interpreting the findings of these interrelated surveys.

General Rules

The following 6 rules apply to the planning of all 8 surveys:

1. For background information, study the literature on oral health needs and resources and on survey principles and procedures (1, 7, 12-15).

2. Consult with a statistician concerning sampling, coding, record forms, analyses of data, and how to present the findings.

3. Consult with another public health dentist, perhaps the regional Public Health Service consultant.

Dr. Striffler is director of the division of dental health, New Mexico Department of Public Health, Santa Fe. This paper is a condensation of one he presented at the Fourth Workshop on Dental Public Health, conducted by the Schools of Public Health and Dentistry of the University of Michigan, April 2-6, 1956. Copies of the proceedings of the workshop are distributed by the publications distribution service of the University of Michigan.

our society and our community can, and probably will, create before long a brave new climate in which to grow old. That is part of the challenge that has inspired so much thought in recent times on the problems of aging. But it is only part of it. Perhaps even more important, and indeed more crucial, is the challenge of keeping before us a vision of what such an aging population can contribute to our modern way of life.

It is perhaps not amiss to remind ourselves again that in everyman's folkways, the world over, the plain folk have aged most successfully when they have discovered and developed for themselves effective places and functions in the very societies in which they are a part. It is very probable that within our highly complex civilization there lie all around us untapped potentials for aging that may be explored and fitted into our times. Herein lies an old frontier that invites new pioneering, and herein, also, lies the Holy Grail for aging.

Summary

The world has never before witnessed such a high proportion of people living on what has been called borrowed time. The problem and the challenge are greater for us than they were

for our forefathers or for our primitive forebears. We are emotionally confused and can't decide how long to stay young or when to get old. Most of us are really younger or older than we think.

In broad historical background, there is more agreement on what old people want than there is agreement on how to get it. Five wishes seem to be shared by aging people everywhere: to live as long as possible, to hoard their waning energies, to share in the continuing affairs of life, to safeguard their seniority rights, and to have as easy and honorable release from life as possible. How to get these five wishes fulfilled in later life has differed greatly around the world.

Human societies solved the problem of a successful old age for a few people long before there was any chance for old age for many people. The old solution to a successful old age was to find a useful and respected place in life and to fill it effectively until near the end—an end that came quickly.

Civilization has created more problems for the aged than it has solved. Now we insure more and more life with less and less in it. The challenge is to find new ways to put interest and zest in aging and for the aged.

Intensive Therapy Curtails Commitment

The enormous and growing population of aging persons has become a matter for extensive official concern in that half the residents of mental institutions are past 65. Controlled studies reported by Dr. Lionel Z. Cosin of Oxford, England, indicate that by setting aside relatively few beds for the intensive treatment of older persons with mental aberrations initially thought severe enough to warrant commitment, the Cowley Road Hospital at Oxford was able to take 125 such patients. Only four had to be committed to mental hospitals. Cosin believes that this method of therapy has cut the admissions to mental hospitals by 80 percent for patients over 65. Many of the mental aberrations are caused by simple circulatory deficiency, and most of the patients respond to good medical management in 20, 30, or 40 days.

—HARALD M. GRANING, M.D., regional medical director with the Public Health Service, Region 5, Chicago, addressing the 1956 Middle States Health Conference.

be in process. If well executed, they may contribute effectively to the public health dentist's project. Such surveys sometimes appear in unexpected places, in State agricultural colleges (21-23) for example. Records from industrial plants, dental schools, or clinics often can be collated and the findings used profitably. Also, the Public Health Service may have conducted surveys in your State.

An example of a survey which was conducted for one purpose but served another is Wishik's survey of handicapped children (24). It brought into focus the particular oral health problems of congenital clefts and malocclusion in addition to other handicapping problems.

Survey Four: Characteristics of the State

The following story illustrates the importance of a survey of the general characteristics of the State and its population:

A few years ago a million-dollar foundation was established to promote the health of the citizens of a certain State. To bring medical and dental care to rural people, several beautiful health centers were built in isolated areas, and the million dollars was soon spent. Today only one of these centers is open, and that one only part time. The population decreased from about 6,000 to less than 1,000 for each health center. There was scarcely anyone left to use the health centers and no one to man them.

A team of cultural anthropologists have stated, "Knowledge of the people is just as important in many aspects of a public health program as is knowledge of medical [dental] science" (25). They listed what should be surveyed from a cultural and socioeconomic standpoint: folkways, income and cost of living, social organization of families, level of education and literacy, political organization, and religious factors. To this list might be added percentage of people receiving public assistance, rural and urban characteristics, and sources of income.

As far as population per se is concerned, the following might be considered: the distribution of the population by geographic area, by age, and by ethnic group, and trends in population growth and movement. The fluoride content of water supplies and climatic factors that

might influence water consumption are other characteristics to be investigated (26).

Many of these characteristics can be surveyed simply by examining the latest Federal census report. Up-to-date population estimates often can be obtained from the State's vital statistics division and verified against estimates by public utilities. In New Mexico, the State university's bureau of business research has provided pertinent information. In some States, commissions or bureaus dealing with economic development can supply useful data.

A survey of the fluoride content of water supplies can be conducted in various ways. In New Mexico, water samples were collected by dentists, pharmacists, and science teachers who volunteered their services. Cooperation was excellent, and considerable interest in fluorides was aroused. Two chemistry teachers made class projects of their part in the survey.

Survey Five: Oral Diseases

Paraphrasing a well-established concept, Knutson gives the reason for a survey of the prevalence and incidence of oral diseases (7): "Effective application of measures for the control of disease depends to a great extent upon knowledge of the manner in which disease occurs in population groups."

Generally, those oral conditions which are most prevalent or which contribute significantly to mortality rates should be surveyed. Specifically, the following hazards, conditions, and diseases should be considered (6, 8, 27, 28):

1. *Dental caries*: The greatest portion of the workload for dentists is the direct or indirect result of dental caries (29).

2. *Periodontal diseases*: Periodontal diseases are a prominent cause of tooth loss in middle and later life (28), and more information on these diseases is needed (30, 31).

3. *Malocclusion*: The inclusion of orthodontic care in dental public health services and surveys of the extent of the problem of malocclusion have been recommended (32).

4. *Congenital oral defects*: The need for early detection of oral clefts has been delineated (24, 32, 33).

5. *Oral cancer*: The need for early detection of oral and related cancer is set forth by Patterson (34), Lloyd (35), and Russell (28).

4. Whenever possible, conduct a pretest or pilot survey.

5. Utilize every opportunity to gain pertinent information.

6. Write out what you plan to do, how you plan to do it, and what you are going to do with the data after they are obtained. In particular, write out definitions for terms; for example, what exactly is meant by DMF or malocclusion. In the process, hazy definitions can be clarified and methods described so that the survey can be repeated at a later date.

Survey One: Subjective Impressions

Despite the difficulty of recording and analyzing subjective impressions or opinions, an attempt to do so may provide valuable information. A social scientist has said that "it is not so much what the facts actually are, but what people believe to be the facts" (16). Knowledge of what people believe to be the facts should help in planning how results of other surveys can be used so that they will be accepted. Also, it may provide leads to what other surveys should be undertaken, and it may be used to some extent in program evaluation.

The opinions of at least three groups are important: the dentists of the State, who not only may be the sole sources of particular information but who also may hold the key to the solution of certain problems; the public, to whom the public health dentist owes first allegiance; and the public health dentist's co-workers.

A written questionnaire is one way of conducting this type of survey. It can be mailed to all the dentists in the State, for example, or handed out at meetings of community organizations. The questionnaire may be a checklist of common oral health problems, or it may contain open-end questions. Parten's book (13) is particularly helpful in designing and using questionnaires. It points out, for instance, that appealing for information as a personal favor has been more productive than offering a reward or stressing some advantage to the respondent.

Another method of learning people's opinions is the workshop (17). *Adult Leadership*, especially the May 1953 issue (18), offers many suggestions for planning such meetings.

Still another method, the least practical but the most accurate, is the personal interview survey in which a well-planned question schedule is used (19). Sometimes a graduate student at a State university will conduct such a survey as work toward an advanced degree.

Whatever the method selected, a social psychologist should help in planning the survey (19).

Survey Two: Knowledge, Attitudes, Practices

A survey of dental health knowledge, attitudes, or practices may be combined with survey one. All that was said about that survey applies to this type.

A recent survey conducted in New Mexico illustrates the why and how of a knowledge survey. Its purpose was to learn the status of dental health information so that a dental health education program could be concentrated on the areas needing attention. Also, the findings would serve as baseline data for measuring the effects of a dental health education program.

A trial questionnaire of 18 questions was developed. It sought to cover the major areas of dental health information, particularly those in which it was suspected that the public is poorly informed. On the basis of a pretest, four questions were eliminated and several were revised. The final form was checked by the department's psychologist for vocabulary level (fifth grade) and format and by the director of vital statistics for machine punchcard tabulations. The test, given to any group interested in it, has been taken by more than 4,000 persons.

Measurement of attitudes and practices is somewhat more difficult than measurement of knowledge, but it can be done. Metzner's article (20) provides excellent background information for this type of survey. Crude estimates of attitudes and practices may be derived from such items as the extent to which candy and sweetened beverages are sold in schools, the number of toothbrushes sold each year, the F component of the DMF rate, and the number of referral cards returned signed by a dentist.

Survey Three: Review of Surveys

Surveys pertinent to a particular facet of oral health may already have been conducted or may

sonnel: dental hygienists, dental assistants, and dental laboratory technicians.

Factors about dentists to be investigated include age, mortality, specialty, postgraduate training, and type of practice (full or part time; public, private, or industrial). Dentist-population ratios should be calculated by trade areas or, where this is not feasible, by city, county, and State. Many of these data can be obtained by a mail questionnaire. Other sources are census reports, the American Dental Directory, and records of State board examiners. Frequently, dental supply houses and dental laboratories can supply up-to-date information on the location of dentists and the type of practice in which they are engaged. In small States, the day-to-day contacts of the public health dentist may elicit such information. Also, many national surveys, particularly those conducted by the American Dental Association, have a sufficient sampling from the more populous States to be directly applicable to those States.

"A Study of Oklahoma's Dental Manpower Requirements" (47) is an excellent guide to surveying a State's dental manpower resources. In particular, it considers the age of dentists as a prime factor in productivity, a point often overlooked. In addition to dentists and dental hygienists, which the Oklahoma study surveyed, one may wish to include dental assistants and laboratory technicians.

Physical facilities to be surveyed include the various types of dental clinics, Federal, State, and local, voluntary and official, mobile and fixed, industrial, school, hospital, and institutional, as well as private offices.

Training facilities for dentists, hygienists, assistants, and technicians also should be taken into account. Finally, facilities such as those for examination of biopsy specimens, treatment of cancer, making of lactobacillus counts, and rehabilitation of oral clefts should be searched out and evaluated.

Survey Seven: Auxiliary Resources

Frequently, there are other resources than strictly dental that will contribute to the solution of dental health problems. Already mentioned are the State agricultural colleges,

which sometimes are engaged in research related to dental health. Colleges and universities may also provide such services as vocational counseling and postgraduate courses for dentists.

Other auxiliary resources are to be found within the official health agency itself. The environmental sanitation division, for example, can supply data on community water supplies and can help in the engineering aspects of fluoridation. The industrial hygienist can provide valuable leads to occupational hazards and to groups available for dental surveys.

The voluntary agencies, too, often can contribute materials or services. Foundations often have funds and personnel waiting for a worthy project. Why shouldn't that project be a dental one?

These resources are usually found by an informal survey; that is, by contacting the right people and asking the right questions.

Survey Eight: Blocks to Solutions

Blocks to the attainment of optimum oral health have been classified as follows: psychological, educational, professional, economic, social, and geographic (48). In public health, a seventh block might be added: administrative. The job of surveying these blocks will have been largely completed if the other surveys described have been made. For example, a survey of the State and its characteristics may reveal hindrances of distance, economics, or cultural patterns (49). Direct surveys of these blocks may, of course, be indicated. For best results, the aid of a social scientist should be enlisted.

Special Problems

It may well be necessary to undertake a special research study during the course of an investigation of a State's oral health status. Often, however, such a study can be dovetailed with other surveys. In New Mexico, for example, a special study (38) was necessitated by the State dental society and the health department's request for an immediate answer to the question, how much fluoride is optimum for New Mexico's climate? To determine preva-

6. *Other diseases and hazards:* Other diseases and hazards pertinent to a particular State may be included; for example, chronic endemic dental fluorosis (6, 26, 36-38), the sequellae of oral trauma (particularly fractured (39) and avulsed incisors), the dental stigmata of congenital syphilis (40, 41), and occupational hazards and diseases (28).

In planning how to conduct the survey, the standard types of survey inspections or examinations may be reviewed and the most pertinent type selected (42). Consideration should be given to the universal record form (43) or, at least, to the possibility of recording data so that they can be translated into terms of the universal form.

Next, whom and where to survey has to be decided. Of necessity, sampling must be considered. Sampling by age, geographic area, socioeconomic level, occupation, cultural pattern, rural and urban area, climate, fluoride content of water, and other characteristics is easier if such characteristics have been delineated for the State by survey four.

Practicality often precludes the use of the best sampling procedures. Since budget and time usually demand that a clinical survey be conducted where people congregate, the dental survey often takes place in a school or industrial establishment. Despite these handicaps, careful planning can still yield worthwhile results. For example, a consolidated school system makes possible the sampling of both rural and urban populations.

Variables that may influence the findings should be reviewed. For example, a physician in New Mexico was sincerely convinced that the contrast in the dental caries prevalence between a fluoride and a nonfluoride city was due to income. When per capita income was shown to be the same for the two cities (38), he capitulated and supported fluoridation for the non-fluoride city.

Planning the actual mechanics of the field survey is the next task. Practices in one State are described in Baker's article (44) and in another in the California manual (45). A general review is given in "A Dental Health Inventory for Maintown" (46). Items to be considered range from dental instruments to wastebaskets. Impression materials and a

clinical camera are among the items that might be included.

An advance trip to the area where the survey is to be conducted is almost essential. Usually, despite voluminous correspondence, an on-the-spot planning meeting with all people concerned is indicated. The public health dentist has the obligation of providing those people with a brief written outline of the purposes and other pertinent information. In surveys of school populations, educational approaches, materials, and aids should be suggested.

The various indexes of oral diseases should be appraised carefully, especially from the standpoint of objectivity, reliability, and reproducibility, before final selection. Too often surveys have been wasted because the examiner *used an index that had meaning only to him.*

Who should perform the clinical examination is debatable. Some public health dentists conclude that whenever possible local dentists should be asked to participate. Others decide that insofar as possible only one examiner should be used. Circumstances may dictate the answer. If the survey is elaborate and detailed, perhaps only one or two examiners should participate. Otherwise, the benefits accruing from the use of local dentists may outweigh the disadvantage of less comparability.

Data for certain oral diseases can be obtained by other methods than the clinical survey. Morbidity and mortality rates for oral cancer and congenital defects, for example, are available from most State offices of vital statistics, subject, of course, to errors of diagnosis and inadequate reporting. The State crippled children's service usually maintains a register of cleft lip and palate cases.

Survey Six: Dental Resources

When the oral health problems have been measured, logically the findings should be compared with the findings of a survey of the resources available for meeting those problems. Then the most effective methods for utilizing and supplementing the resources can be determined.

Dentists are the chief manpower resources, but not to be forgotten are the auxiliary per-

lence of fluorosis, the first survey was conducted among junior high school students in communities which, according to previous routine chemical analyses of the water, differed as to fluoride level. This study was integrated with a survey of other dental diseases.

Analysis and Interpretation of Data

Since all the surveys outlined in this paper are interrelated, some of them even being carried on simultaneously, plans for statistical analyses of the data should be laid early in the project. Sometimes findings from one survey will contradict the findings of another, and the differences must be resolved. Conversely, the results of one survey may reinforce those of another. It is here that the help of an expert statistician is invaluable.

Planning for the interpretation of the results to the profession and the public also should begin early, and the health educator should participate. Phair has challenged public health dentists to get away from the traditional technical interpretation of data and to explain findings in simple, meaningful terms (15). Unless plans are made to report and utilize the findings in a profitable manner (16, 19, 50), the surveys might as well not be done.

Summary

If one is to plan, execute, and evaluate State dental health programs in a logical manner, comprehensive information concerning the State's dental health needs and its resources is indispensable.

What do the people consider to be the oral health problems? What do the members of the dental profession see as the problems?

What is needed in the way of health education? What do people know about dental health? What do they do about it?

What is the distribution of the population by geographic area, by age, and by ethnic group? What are the trends in population growth and movement? What about the fluoride content of the water supplies?

What is the prevalence of the major oral diseases?

How many dentists are there in official agen-

cies? in private practice? in industry? How many auxiliary personnel?

What is the status of physical facilities?

Are there blocks to the attainment of optimum oral health?

Some of these questions can be answered simply by a search and study of existing source materials. Others require more formal surveys, such as questionnaires, personal interviews, or even clinical examinations. Then the data obtained in answer to specific questions must be analyzed and integrated to provide a complete picture of the State's dental health status.

At first glance the job may appear to be too overwhelming to tackle, but the State dental public health director and his staff can, with the help of others, accomplish it, bit by bit. Actually, of course, surveying is a continuing process, for conditions next year will inevitably differ from conditions this year.

Analysis of Diabetes Screening Costs in a County Health Department

By ANDREW C. FLECK, Jr., M.D., M.P.H., and RITA C. CHISHOLM, R.N., M.A.

THE DECLINE in communicable disease morbidity and mortality has directed community health efforts to the prevention of chronic diseases. One form of action is the community-supported diabetes screening clinic designed to screen a hyperglycemic group by testing blood or urine specimens. The clinic may include a detection as well as a screening service (1).

The followup of hyperglycemic groups defined by screening tests shows that from 0.5 to 1.0 percent of the population screened have previously undiagnosed diabetes. No data are available, however, for evaluating the sensitivity or specificity of these screening techniques (2).

The earlier detection of diabetes in these clinics may arrest the progression of diabetes into disability and premature death; it is therefore recognized to be valuable as a secondary prevention which should be included in every organized public health program.

Three hypotheses generally accepted as the basis for operating a diabetes detection service are: (a) that diabetes mellitus is frequently unrecognized and asymptomatic; (b) that earlier diagnosis and management of diabetes improves prognosis; and (c) that untreated diabetics are abnormally hyperglycemic after food intake. A fourth hypothesis which is not generally accepted is that the postprandial hyperglycemic population can be economically and efficiently

screened from the general population by a community-operated clinic service.

The Rensselaer County Health Department tested this fourth hypothesis by relating costs to results in its diabetes screening clinic started in September 1954 in Troy, N. Y.

The objective of the diabetes screening clinic is the discovery of a hyperglycemic population that can be referred to physicians for detection of previously unknown diabetes. To demonstrate that this objective is being attained efficiently and economically we offer three indexes of results: number of persons screened, number of hyperglycemic persons discovered, and number of previously unknown diabetics detected.

During the first 4 months of operation in Troy, when methods were still relatively inefficient, 525 persons were screened. Eighteen were found to have capillary blood sugar levels greater than 160 mg. Five of these were diagnosed as previously unknown diabetics.

In 1955, under routine conditions, 1,438 persons participated. Forty-three persons were screened as hyperglycemic, and 13 of this group were diagnosed as previously unknown cases of diabetes (table 1).

Screening Methods

The screening clinics are conducted on a nonappointment basis 4 times a week for 1 hour. The health center is centrally located in Troy, a city of 73,768 persons. Promotion during 1955 was limited to newspaper and word-of-mouth publicity.

Dr. Fleck is commissioner of health and Miss Chisholm is supervising public health nurse of the Rensselaer County Health Department, Troy, N. Y.

Converts to Hospital Delivery

When the health center opened in the Arab village of Tira, public health nurses met with little success in inducing pregnant women to have their babies in the hospital. Women in the Little Triangle villages have always been delivered at home by *dayas*, women who practice midwifery under hazardous conditions.

When a woman went into labor recently, she called for help from the midwife licensed by the Tira Health Center. The midwife delivered the baby at home in the presence of the local *daya* because she was unable to persuade the mother to come to the center hospital.

A second woman went into labor shortly thereafter, and she too called for the licensed midwife. This time the midwife refused to deliver the child at home and succeeded in convincing the husband that his child should be born in the hospital. The center first had to agree that the *daya* would be present, the male physician would be absent, and the husband and others in the family could remain in the center for the birth.

Pleased with the care and treatment given to his wife and child, the father made an unprecedented

concession. He agreed that the mother and baby and all the family members could be photographed.

Word of the experience spread. Within the next 2 weeks, 12 women were delivered in the hospital. The task of the nurses in inducing women to have hospital deliveries has been easier ever since.

—JACOB H. LANDES, M.D., *acting chief, Health and Sanitation Division, United States Operations Mission, Israel.*

Sanitation School

The Palasht Sanitation School fulfills a basic sanitation need in the Middle East by providing practical training in the villages. Among the 170 sanitarians trained for the Ministry of Health, other government departments, and private agencies since the opening of the school in 1952 are 6 Afghans who are putting their education into practice in their own country.

Students attend classes in the morning, work outside in the afternoon. Half of their classtime is devoted to work in the laboratory. Among the subjects covered in the 7-month curriculum are bacteriology and parasitology, excreta disposal, refuse collection and disposal, milk and food sanitation, insect and rodent control, camp and swimming pool sanitation, vital statistics, and government organization in Iran.

—ALBERT P. KNIGHT, M.D., *formerly chief, Public Health Division, United States Operations Mission, Iran.*

reports were made voluntarily by the physicians. The other half were obtained by public health nurses. Diagnostic criteria used by physicians for establishing or excluding diabetes were quite variable. Among 27 suspects definitely diagnosed as diabetic or nondiabetic by family physicians, 13 diagnoses were made on the basis of 1 fasting blood sugar, 2 on the basis of negative urines, and 1 on the basis of a glucose tolerance test; 11 indicated that no glucose tolerance test was performed but did not indicate what criteria were used. The followup results taken at face value indicate the need for the inclusion of a detection service in the clinic with referrals for treatment on the basis of uniform diagnostic criteria.

Program Costs

The collection of cost data was a byproduct of a departmentwide performance budgeting system installed by the New York State Temporary Commission on Fiscal Affairs of State Government in 1954 (4). Two basic types of cost are identified, fixed and variable. Variable costs are incurred in direct proportion to patient participation. Fixed costs occur in setting up and being ready to start; they are costs which are not appreciably affected by patient volume. For example, the cost of the testing equipment is fixed and the cost of testing supplies is a variable cost. The sum of fixed and variable costs is the operating cost.

In calculating a cost per unit of result, it is important to have the distinctions between

| Fixed costs ¹ | 206.91 |
| Operating cost for 1955 | \$1,228.28 |

¹ Equipment depreciation and replacement cost determined in 1954.

fixed, variable, and operating costs clearly in mind. For example, if a new program is planned on a 5- to 10-year operating basis, the operating cost is the most significant figure. On the other hand, if the program is being abandoned for economy reasons, the variable cost looms important since it is the only cost which will be saved.

Our operating cost was determined first by depreciating the equipment on a 10-year straight-line basis and the other fixed costs on a 5-year replacement basis. These figures were then added to the sum of all variable costs. The operating cost did not include the cost of services in the basic health department. These service costs could not be eliminated if the program were abandoned nor did they need augmenting when the program started. They included clinic space and public health nurse followup service.

The sum of \$1,908.71 was spent in the 4

² Capillary blood levels above 160 mg. percent blood sugar content.

A clerk-receptionist registers persons attending the clinic, and determines whether they came for a diabetes test or a chest X-ray. She completes a record card for the desired test and offers the additional screening procedure to the patient. A brief explanation of the procedure and objective of the screening tests is given by the receptionist to induce the patient to participate in both tests. The registration card contains, in addition to the usual identifying information, any family history of diabetes, height, weight, approximate weight 5 years before, time since eating last meal, and the source of referral. The patient is then directed to the X-ray room or the diabetes testing room.

For diabetes screening, the technician copies on the test tube the code number appearing on the registration card which the patient has brought with him. Testing procedure begins with the collection of 0.1125 cc. of capillary blood from the fingertip, which is mixed with 5 cc. of distilled water diluent. The sample is then tested with standardized reagent tablets at a screening level of 160 mg. percent of blood glucose according to the method of Wilkerson-Heftmann (3). No urine specimens are taken, and no retesting service provided. At the same session a 4- by 5-inch stereoscopic photofluoro-

graphic chest X-ray is taken if the patient has consented to the additional screening procedure. Test results are then recorded on the registration card. Since both tests are performed in a few minutes, the average length of stay in the clinic is from 10 to 15 minutes.

The patient is advised both verbally and by a brochure that reports of both procedures, accompanied by one-half of the 4- by 5-inch stereoscopic X-ray film, will be sent to the family physician. Patients with positive tests are referred to their physicians for diagnostic study. The physician is then requested to report his diabetes diagnostic findings to the clinic on an enclosed self-addressed coded postcard when the diabetes test is positive. If the diabetes test is positive or if there are abnormal X-ray findings, the individual is sent a letter advising him to consult his physician. In general, the agency follows up with nursing service all cases with positive screening tests until a diagnosis is established or excluded.

Problems in Operation

On intake in the clinic, 637 persons had not eaten within 2 hours. One hundred sixty-five persons attended 4 to 6 hours after eating regardless of the timing of the clinics. Only 812 had eaten within 2 hours. To meet this problem we are now exploring the specificity and sensitivity of screening at two different levels: 160 mg. if the specimen is postprandial or 130 mg. if it has been more than 2 hours since the last meal.

Acceptance of both screening procedures is greatly influenced by the attitude and interest of the registration clerk. When the same clerk served at each clinic the participation improved. We do not recommend the use of a public health nurse for registration because of the greater cost and the fact that the nurse's time is better spent in promotional and educational activity in the field.

The only bottleneck encountered during the tests was in developing enough skill to draw 0.1125 cc. of blood without undue "milking" of the finger. This problem was overcome after a few sessions. For rapid testing, a clinitron is used (4).

During 1955, only 50 percent of the followup

The 1953 mass chest X-ray survey in Pittsburgh and Allegheny County, Pa., accurately identified an estimated 40 cases of primary lung cancer in about 802,000 residents examined.

Followup Study of 844 Neoplasm Suspects Identified in a Mass Chest X-ray Survey

By C. DEAN McCLURE, M.D.

STATISTICAL and clinical studies of the effectiveness of mass chest X-ray surveys in finding primary lung cancer have been reported since 1950 (1-6). Because of continued and rather widespread interest in this subject, the results of a similar study carried out as part of the followup of the 1953 mass chest X-ray survey in Pittsburgh and Allegheny County, Pa., are recorded here. In this study, 844 persons classified on the basis of survey films as neoplasm suspects were followed for 30 months to determine their clinical diagnoses and mortality experience.

As stated by the Pittsburgh and Allegheny County X-ray Survey Foundation, the primary purpose of the survey was to screen the adult population (over 15 years of age) of Pittsburgh and Allegheny County for undiagnosed active

tuberculosis. An important secondary purpose was to screen the group for other active chest diseases, including neoplasms.

Survey Procedures

All persons participating in the survey initially had 70-mm. postero-anterior chest films. These were read for abnormalities by at least 1 member of a team of 4 Public Health Service physicians. Participants whose films were considered negative were so notified by mail. Resident participants whose films were technically unsatisfactory or showed abnormal findings were requested to report to survey headquarters for confirmatory films.

On return for a confirmatory film, the participant was interviewed by a clerk, and basic

Dr. McClure is a research fellow in epidemiology at the Graduate School of Public Health, University of Pittsburgh. He was assigned to the Pittsburgh area in 1953 by the National Cancer Institute, Public Health Service, to conduct epidemiological studies of lung cancer. At the direction of the Pittsburgh Department of Public Health, he conducted the long-term followup study of neoplasm suspects reported here.

Dr. C. Howard Marcy, secretary of the Pittsburgh and Allegheny County X-ray Survey Foundation, and Dr. Robert Anderson, at the time of the study, chief of the Tuberculosis Control Division, Public

Health Service, made available the original survey records. Dr. Merle Bundy, then director of tuberculosis control, Pittsburgh Department of Public Health, and secretary, Allegheny County Chapter, American Cancer Society, assisted in the study planning.

Dr. Mary E. Patno, office of biostatistics, Pittsburgh Department of Public Health, tabulated the general survey data. J. William Lloyd of the same office made the special tabulations of the neoplasm suspects. Miss Bernadette Brady of the Public Health Service assisted with the special followup of the neoplasm suspects.

Table 4. Relationship of diabetes screening costs to result, Rensselaer County Health Department, 1955

| Type of cost | Total expense | Cost per person screened (1,438) | Cost per suspect (43) | Cost per new case detected (13) |
|--|---------------|----------------------------------|-----------------------|---------------------------------|
| Fixed cost (depreciation and replacement) ¹ ----- | \$206. 91 | \$0. 14 | \$4. 80 | \$15. 90 |
| Variable costs----- | 1, 021. 37 | . 71 | 23. 75 | 78. 56 |
| Operating cost----- | \$1, 228. 28 | \$0. 85 | \$28. 00 | \$92. 50 |

¹ Gross fixed costs for 1954 were \$1,534.56.

months it took to establish the clinic on a routine basis. Table 2 shows how this cost was distributed as fixed or variable.

Relationship of Cost to Result

The operating cost for diabetes screening during the 4 months of operation in 1954 was \$581.06. Five previously undiagnosed diabetes were detected at an operating cost of \$116.21 each.

Only variable costs were incurred during 1955. They are listed in table 3 exactly as the obligations were incurred. This time sequence should give the reader an insight into the development of the operation.

In 1954 there were no expenditures for certain supplies, such as cotton and alcohol, which were drawn from existing stocks. Such items are included in the 1955 expenses and an inventory was left at the end of that year. No adjustment was made since the inventories were small and a cost adjustment would not significantly alter the analysis.

In using these data we find that the operating cost (including the annual fixed replacement and depreciation cost determined in 1954) for

diabetes screening in 1955 was \$1,228.28. How the various component costs contained within the operating cost relate to the results is shown in table 4. Most significant is the fact that the cost of detecting a case of diabetes is \$92.50 under present patient volume. This should approach the variable cost of \$78.56 per new case as better promotion of the program is attained. In the first 4 months of operation in 1954 a similar variable cost of \$74.00 was obtained.

Summary

Diabetes screening procedures for promotion of earlier detection are a recognized form of secondary prevention of disease. In a community-operated screening clinic, a post-prandial hyperglycemic population can be delineated from the general population by capillary blood sugar determination at a cost of approximately 85 cents per person screened. One year's experience has shown that the cost of detecting one previously unknown case of diabetes should approach a cost of \$75 per new case found.

**Results of the Mass Chest X-ray Survey in Pittsburgh and Allegheny County, Pa.,
March 25–September 25, 1953**

¹Based on interpretation of original 70-mm. films (including 343 duplicates, triplicates, etc.).

²Residence outside survey area.

³Based on interpretation of confirmatory 14" x 17" or 70-mm. films (including 44 large films taken on persons other than those recalled).

NOTE: Figures in parentheses are percentages based on total survey population.

data, including the name of the participant's private physician, were recorded on an epidemiology worksheet. All persons responding to recall who were suspected on the basis of the original 70-mm. film of having tuberculosis, neoplasms, or "other chest disease" routinely had 14" x 17" postero-anterior confirmatory films. Lateral or oblique views were filmed whenever the film interpreter requested them. All persons suspected of having cardiovascular disease had 70-mm. confirmatory films.

Four main categories of chest disease suspects were referred to their private physicians on the basis of the confirmatory film or, if the participant failed to respond to recall, on the basis of medical review of the original 70-mm. film. Nonrespondents were referred only when their 70-mm. films were regarded by the medical review committee as warranting further clinical study. For these cases, the basic epidemiological data were gathered through telephone calls or visits by nurses to the participants. Each referral was accompanied by the partially completed epidemiology worksheet. The physician was requested to add to this the final diagnosis of the patient's chest condition when it had been determined and to return the form to survey headquarters as soon as possible. If the private physician referred the patient to another physician for diagnosis, a duplicate epidemiology form was sent to the new physician with the same request.

The epidemiology forms provided most of the data upon which the clinical findings reported in the following section are based. However, additional followup procedures, including telephone calls and special letters to the physicians, were employed by the survey personnel and the local unit of the American Cancer Society to determine clinical diagnoses for the 784 neoplasm suspects who were referred. Of the 844 neoplasm suspects included in this study, 60 were not referred because they could not be located, had died, or were uncooperative.

General Survey Results

The total number of persons X-rayed in the survey was 864,790, which represents approximately 75 percent of the total population of Allegheny County eligible for participation. However, that figure includes many visitors to the county and a few persons who were X-rayed more than once. At present, the best estimate of the number of visitors and multiple films is approximately 62,759, which leaves a total of 802,031 residents X-rayed. This estimate is based on the percentage of visitors and multiple films noted in the recall population.

Because of the size of the task, the age-sex rates of participation have not yet been determined. Thompson and Pell, however, have estimated the age-sex participation rates for approximately 80,000 residents of the Arsenal

² October 1954 through March 1956.

confirmatory films. Of those recalled, 26,774 (84.8 percent of recall population) responded.

Of the total original 70-mm. films, 16,327 (1.9 percent) were interpreted by the reader as suspected tuberculosis. Similarly, 4,116 (0.5 percent) were classified as suspected cardiovascular disease; 1,183 (0.14 percent) as suspected neoplasm; and 10,281 (1.2 percent) as suspected other chest disease. On the basis of the confirmatory films, the yield of suspected tuberculosis was reduced to 10,739, or 1.2 percent of the total survey population. Likewise, the yield of suspected cardiovascular disease was reduced to 3,159 (0.4 percent); the yield of suspected neoplasm to 699 (0.08 percent); and the yield of suspected other chest disease to 4,460 (0.5 percent). Interestingly, 7,761 participants, 0.9 percent of the total survey population, originally had X-ray findings classified as abnormal but were considered "essentially negative" after their confirmatory X-rays.

Clinical Diagnoses Reported

A total of 19,130 persons were referred to their private physicians for diagnosis (table 2). These include, in addition to those who had ab-

normal findings on the confirmatory film, some persons who were referred on the basis of their original small X-rays. During the survey followup period, April 10, 1953-June 30, 1954, clinical diagnoses were reported to survey headquarters for 10,693, or 55.9 percent, of those referred. No report of clinical findings was received for the remaining 8,437 persons referred.

The most common diagnosis reported was tuberculosis (all stages, including inactive cases), which was returned for 4,928 persons (46.1 percent). A diagnosis of cardiovascular disease was reported for 1,679 persons (15.7 percent); a diagnosis of neoplasm for 270 (2.5 percent); and a diagnosis of "other chest disease" for 2,485 (23.2 percent). A clinical impression of essentially negative was reported for 1,331 persons. This figure represents 12.4 percent of those for whom clinical diagnoses were received and 7.0 percent of the 19,130 referrals.

Study of Neoplasm Suspects

For the 844 persons identified in the survey as neoplasm suspects, a Public Health Service research team undertook special followup pro-

health district in Pittsburgh (7). By applying these rates to the estimated age-sex distribution for the 1953 population of Allegheny County, the number of residents X-rayed in each age-sex group can be calculated, as shown in table 1. According to this method, the total number of resident participants was 686,587, considerably fewer than the number found by subtracting the estimated number of visitors and multiple films. However, Thompson and Pell have stated that they felt the participation

rates in the Arsenal health district were lower than those for many other sections of the city and county.

X-ray Findings

As shown in the accompanying diagram, 4 percent of the total survey population were considered to have abnormal X-ray findings on the basis of the original 70-mm. films. Of these, 31,567 (all those with abnormal findings who were residents of the county) were recalled for

Table 2. Clinical diagnoses reported during survey followup period (April 10, 1953-June 30, 1954), according to type of disease suspected at time of referral: 1953 mass chest X-ray survey in Pittsburgh and Allegheny County, Pa.

the majority of these moved within Allegheny County during the 30-month period; however, none appeared on the county death lists for that period.

A total of 126 deaths are known to have occurred among the neoplasm suspects during the 30-month followup period. This number is considered the minimum 30-month mortality estimate for the group since it is unlikely that all deaths were identified in this followup study. Eighty-three of the deaths occurred by the end of September 1954, giving an average annual mortality of 9.8 percent. Among the 46 persons reported to have primary lung cancer, there were 28 deaths (60.9 percent) during that period. The mortality among the non-lung-cancer patients was only 6.9 percent. The average annual mortality for all categories decreased during the second report period. The 30-month mortality figures show the highest rate for lung cancer patients.

Of the 126 known deaths during the 30-month followup period, 44 were due to lung cancer (tables 5 and 6). Cancers of other sites were the causes of 33 additional deaths, while the remaining 49 deaths were ascribed to causes other than cancer or to unknown causes. Thus, the minimum 30-month mortality among the neoplasm suspects by cause of death was 5.2 percent for lung cancer, 3.9 percent for cancers of

other sites, and 5.8 percent for all other or unknown causes. Most of the lung cancer deaths (79.5 percent) occurred by the end of 1954. Non-lung-cancer deaths, however, were more evenly distributed over the 30-month followup period.

The 30-month lung cancer mortality rate was highest (63.0 percent) among those cases diagnosed as primary lung cancer (table 5). However, 10 of the 388 persons with clinical diagnoses of either benign neoplasm or "other chest disease" also died of lung cancer during this period. Similarly, most of the lung cancer deaths (88.4 percent) occurred among those who were suspected of having lung tumors at the time of referral (table 6). The 30-month lung cancer mortality for this group was 7.4 percent. The group suspected of having lung tumors had a 30-month mortality rate for all causes of death of 16.4 percent.

Discussion

The crude yields of abnormal films, of suspected tuberculosis, and of suspected neoplasm from the survey of Pittsburgh and Allegheny County are commensurate with confirmatory findings reported for other mass chest X-ray surveys (1-5). For all categories of disease, there were wide variations between the readings

cedures, including abstracting of hospital and office records, examination of death certificates, and search of county death lists. By these procedures, clinical diagnoses were obtained for an additional 106 of the neoplasm suspects, and new diagnoses were found for a number of the 613 suspects for whom clinical findings had been reported during the survey followup period.

Clinical Diagnoses

The most frequent diagnosis for the neoplasm suspects was some type of neoplasm, as shown in table 3. (This table includes the clinical findings obtained by the special followup procedures; therefore, the data differ from those in table 2.) Most of the neoplasms, however, were benign chest tumors. Only 75 (8.9 percent) of all the neoplasm suspects were reported to have primary malignancies of the chest, and only 46 (5.5 percent) had diagnoses of primary lung cancer. Other yields for the neoplasm

suspects included 127 (15.0 percent) cases of tuberculosis, 32 (3.8 percent) cases of cardiovascular disease, and 155 (18.4 percent) cases of "other chest disease." For 70 (8.3 percent) of the neoplasm suspects, the diagnosis was "essentially negative." No report of clinical findings was obtained for 125 (which includes the 60 who were not referred to physicians), or 14.8 percent of the suspects.

Mortality Experience

The survival status at the end of two report periods was determined for each category of clinical diagnosis (table 4). The first report period covers the first year following the end of the X-ray survey, that is, from October 1953 through September 1954. The second report period includes the 18 months from October 1954 through March 1956. Efforts to obtain survival data on the 153 persons classified as "status unknown" have been prolonged because

than those in the lung cancer diagnostic category. For all persons in these other diagnostic groups who died of lung cancer, the lesions present at the time of the survey X-ray appeared to be small. For some of them, the absence of specific symptoms delayed a definitive diagnostic workup until the lesion had become inoperable. In this survey, the difficulty of clinically distinguishing between neoplasms, tuberculosis, or other chest disease appeared to be most accentuated when the X-ray revealed small or rather poorly defined lesions in the lungs.

Each of the 8 surviving lung cancer patients who had pneumonectomies had an opacity measuring 3 cm. or more on the 14" x 17" survey X-ray. All other diagnostic aids employed, including cytological examination of sputum and bronchial washings, were negative for each of these patients. Only at thoracotomy was a definitive diagnosis established.

The 30-month mortality experience of the neoplasm suspects according to the site suspected at the time of referral further demonstrates the difficulty of finding salvageable lung cancer cases (table 6). The distribution of the 126 known deaths shows a high mortality from lung cancer among those persons originally suspected of having lung tumors. In fact, the group suspected of having lung tumors had rather high mortality from all causes of death. However, the deaths from cancer began to occur earlier than did the deaths from other causes.

The relatively high lung cancer mortality among the lung tumor suspects, together with the fact that 7 of the 8 patients who had pneumonectomies belonged to the lung tumor suspect group, indicates that the X-ray methods employed in the survey to find cases of primary lung cancer were of limited but definite effectiveness. Had there been greater survey participation by older men, it is very probable that the ratio of primary lung cancer cases to lung tumor suspects would have been greater.

Summary

A mass chest X-ray survey was undertaken in 1953 in Pittsburgh and Allegheny County, Pa., primarily to find undiagnosed active tuberculosis and secondarily to detect other chest diseases. According to the estimated age-sex

distribution of the survey participants, participation by older men was relatively poor. Thus, the effectiveness of the survey for detecting primary lung cancer was severely limited.

Of about 802,000 resident participants, 844 were classified as neoplasm suspects on the basis of 14" x 17" confirmatory films or 70-mm. original films. By the use of the usual followup procedures plus special measures, clinical diagnoses were obtained for 91.5 percent of the 784 neoplasm suspects referred to private physicians, and the mortality experience during a 30-month period was learned for 81.9 percent of the 844.

In both the group with clinical diagnoses of primary lung cancer and the group suspected on the basis of the X-rays of having lung tumors, the mortality rate was high and death occurred in a short time. These findings demonstrate the rapidly fatal course of lung cancer following detection by X-ray or clinical diagnosis. Eight of the fifteen survivors in the lung cancer diagnostic category had pneumonectomies. For each of these eight, the survey X-ray showed rather large lesions which ordinarily would not be considered "early," but apparently the malignant process was amenable to surgery.

Deaths due to primary lung cancer also occurred among persons with clinical diagnoses of benign neoplasm or "other chest disease." These deaths occurred somewhat later than the lung cancer deaths in the lung cancer diagnostic group. For most of these persons, the presumably misdiagnosed X-ray lesions appeared small or not well defined. The difficulty of distinguishing on an X-ray film between lung tumors, tuberculosis, and "other chest disease" is indicated by the fact that among the persons suspected of having lung tumors, the percentage with clinical diagnoses of chest neoplasm was no greater than the percentages with clinical diagnoses of tuberculosis or "other chest disease." However, the comparability of the clinical findings is difficult to evaluate because of the probably different diagnostic criteria used by the physicians examining the patients.

According to information available thus far, the mass X-ray survey accurately detected an estimated 40 cases of primary lung cancer

of the small and the large X-ray films. Such variations have been noted repeatedly by radiologists, and it has been assumed that the larger films can be interpreted more accurately for all types of chest disease. Thus, the reasons for taking large confirmatory X-rays in mass surveys are to reduce the number of false positives and to decrease the amount of unnecessary survey case followup. Whether or not large films are better than 70-mm. films from the standpoint of detecting neoplasms has apparently not been investigated, and the data presented here are not satisfactory for answering that question.

If the figures in table 1 represent even roughly the age-sex distribution of the survey participants, only 40 percent of the total X-rays of men were taken among those 45 years of age or older. Also, it is in the older age groups that the participation rate declines to less than 55 percent. Since a significant number of cases of primary lung cancer would be expected only among men over 45 years old, the effectiveness of the X-ray survey in finding cases of this disease was severely limited.

The clinical data presented are based largely upon the findings reported by physicians in response to the survey followup procedures. As such, these data are subject to many of the same biases recognized and reported for previous mass X-ray surveys. It is significant that by June 30, 1954, at least 10 months after all referrals were made, clinical diagnoses were reported for only 55.9 percent of the total number of persons referred. By this same date, clinical diagnoses were established for 78.2 percent of the neoplasm suspects. This higher percentage undoubtedly is due to the additional followup efforts made for this group. As a result of the special followup by a Public Health Service team, diagnoses were obtained for an additional 106 of the neoplasm suspects, bringing the percentage up to 91.5.

The yield of 5.5 percent for primary lung cancer among the neoplasm suspects is small in comparison with the yields for other diagnoses (table 3). This yield increases but slightly, to 7.6 percent, when only those persons suspected of having lung tumors are considered. The difficulty of accurately discriminating on X-ray between lung tumors, tuberculosis, and other lung diseases is reflected by the fact that among

the lung tumor suspects the percentage with clinical diagnoses of lung tumor was no greater than the percentage with clinical diagnoses of tuberculosis or "other chest disease." Accurate appraisal of any differences among these lung disease categories is obscured by the fact that different diagnostic criteria were undoubtedly applied by the many physicians reporting clinical findings. For several persons, the clinical diagnoses reported to survey headquarters had to be changed in the light of later findings noted by the physicians.

The mortality experience of the neoplasm suspects shows clearly the rapidly fatal course for the majority of the reported primary lung cancer cases (table 4). Twenty-eight of the forty-six persons with primary lung cancer died within 12 months after the end of the survey, and 31, within 30 months. Some question might be raised as to the accuracy of the diagnosis for the 15 survivors. For 8 of these, the diagnosis was confirmed microscopically, and the patients had pneumonectomies with apparently curative results. For the remaining 7 the diagnosis was based on X-rays alone.

The mortality rates were considerably higher for persons reported to have either primary or metastatic malignancies of the lungs than for those in the other diagnostic categories (table 4). Also, the majority of the deaths in the groups with malignancies occurred much earlier than the deaths in the other diagnostic groups. This observed early mortality suggests that many of the reported primary and metastatic lung cancer cases were brought to medical attention by the survey at a late stage of the disease. It is likely that extreme pathological changes were present at the time of the survey X-ray; consequently, the mortality rate was high. Deaths due to causes other than cancer occurred more frequently among persons in the non-lung-cancer diagnostic groups. This is probably due to the rapidly fatal course of both primary and metastatic lung cancers after diagnosis.

Deaths due to primary lung cancer occurred among persons in some of the other diagnostic categories; for example, the benign neoplasm and the "other chest disease" groups (table 5). These deaths, however, occurred somewhat later

A Year's Experience With a Nationwide TPI Testing Service

By HILFRED N. BOSSAK, B.S.,
VIRGINIA H. FALCONE, B.S.,
and AD HARRIS

SINCE THE ADVENT of the *Treponema pallidum* immobilization (TPI) test, laboratories throughout the world have been using this test procedure either experimentally as a research tool or as a diagnostic aid. However, numerous modifications of the original Nelson and Mayer method (1) have been adopted. A World Health Organization report (2) containing information from 25 laboratories performing the TPI test indicates little uniformity among the techniques employed.

Previous reports from the Venereal Disease Research Laboratory (3, 4) have shown that the reactivity level of the TPI test may be affected by alteration of the complement concentration in the test, by an increase in the amount of thioglycolate in the survival medium, or by failure to maintain an adequate and constant number of organisms in the treponeme suspension used as the test antigen. The technique employed at the laboratory during the period of this report used a concentration of complement four times greater than that recommended in the original Nelson and Mayer procedure, a fivefold increase in the concentration of thioglycolate, and a constant concentration of 15 organisms per high-dry (HD) field. As a result of the adoption of these and other selected modifications (5, 6) the TPI test has been in daily operation in the Venereal Disease Research Laboratory as a routine procedure for more than 18 months, with test runs including as many as 60 specimens per day.

In response to increasing requests for performance of the TPI test from physicians

throughout the United States and in the absence of adequate facilities for performing this procedure elsewhere, a TPI testing service was made available by the Venereal Disease Research Laboratory on a nationwide basis. Beginning January 1, 1955, State and Territorial departments of health laboratories and Public Health Service installations were included.

The purpose of this report is to evaluate a 1-year experience with this nationwide service, and to present the findings obtained by testing more than 2,400 serum specimens submitted through the State and Territorial departments of health laboratories.

During the period January 1 to December 31, 1955, a total of 2,875 serums were received from these sources. Of these, 2,487 were tested, 150 were bacterially contaminated and were unsatisfactory for testing, 15 had leaked or the tubes had been broken in transit, and 223 were not tested until after December 31, 1955, and therefore were not included in this report. The number of specimens submitted for testing increased sharply as the availability of the service was more widely publicized. During the first 6 months, 704 specimens were received. However, during the next 3 months more than 1½ times as many, or 1,140 serums, were received for testing. During the last 3 months of the year approximately the same number, namely, 1,031 specimens, were submitted for testing. The totals for the last 6 months of the year represented an actual testing load of 350 to 400 specimens per month.

Source of Specimens

Although serum specimens from other sources were tested during this period, only those from the laboratories of State departments of health are referred to in this report since each of these specimens was accompanied by a clinical data sheet listing pertinent facts of the patient's history. The data included evidence of history of treponematosis, such as previous diagnosis, therapy for syphilis, and evidence of syphilitic infection in the family; record of known serologic tests for syphilis; evidence of other diseases, especially those presumed to elicit nonspecific reactions in serologic tests for syphilis; and the physician's opinion

Mr. Bossak and Mrs. Falcone are bacteriologists and Mr. Harris is director, Venereal Disease Research Laboratory, Public Health Service, Chamblee, Ga.

among the participating residents of Pittsburgh and Allegheny County. Just how efficiently this was done cannot be answered from the data presented here, but certain deficiencies in the methods employed are evident.

Syphilis Serology Courses

Nine laboratory refresher courses will be offered at the Venereal Disease Research Laboratory of the Public Health Service in Chamblee, Ga., September 1957 through May 1958, according to the following schedule:

Serology of syphilis: September 9-20, 1957; December 2-13, 1957; February 17-27, 1958; May 5-16, 1958.

Tests for syphilis using *Treponema pallidum*: October 7-18, 1957; March 10-21, 1958.

Control of syphilis serology by the regional laboratory: October 21-November 1, 1957; April 7-18, 1958.

The public health laboratory in venereal disease control: March 24-28, 1958.

The four courses in serology of syphilis consist of lecture, demonstration, and participation periods covering the most widely used procedures outlined in the 1955 edition of the *Manual of Serologic Tests for Syphilis*.

The two courses in *Treponema pallidum* tests for syphilis include instruction in the performance of the *T. pallidum* immobilization and complement fixation tests and other procedures.

Two courses in control of syphilis serology by the regional laboratory are designed for assistant laboratory directors and senior laboratory staff members. They include review of serologic evaluation programs, laboratory visits and field "workshop" procedures, and discussion of new methods using treponemal antigens.

The course on the public health laboratory in venereal disease control, designed for laboratory directors, includes discussion and demonstration of new procedures and use of laboratory aids in diagnosing venereal diseases.

Applications for the courses must be approved by the State health officer or laboratory director, by the medical officer in charge if the applicant is a Federal employee, or by the sponsoring organization of applicants from other countries. Reservations should be made not later than 1 month before the starting date of the course. Application forms may be obtained by writing to: Director, Venereal Disease Research Laboratory, Venereal Disease Branch, Communicable Disease Center, Public Health Service, P. O. Box 185, Chamblee, Ga.

should be noted, however, that the patients in this study represented diagnostic problem cases, and the relationship observed between TPI test result and sex of the patient is not necessarily representative of random population groups.

Complete data relating diagnoses and patient histories to the TPI test results were available for 2,449 serum specimens (table 3). Of these patients, 1,772, or approximately 72 percent, were considered by the physicians submitting the serum specimens to be biologic false-positive (BFP) reactors in other tests for syphilis. In this group 137 patients had histories of a previous diagnosis of syphilis, but serum from 40 of these patients was nonreactive in the TPI test.

Of the 1,772 serum specimens giving biologic false-positive reactions, 718, or 40.5 percent, produced reactive or weakly reactive results in the TPI test. The positive findings obtained with other serologic tests for syphilis

in the absence of clinical evidence of syphilitic infection must be referred to either as latent syphilis or as false-positive test results. As determined from data furnished in the clinical data sheets accompanying the specimen of serum, 38 percent of those meeting these criteria gave reactive results in the TPI test. If it is presumed that a reactive result in the TPI test can only be caused by one of the treponemal infections, past or present, then the TPI test would be 100 percent specific by definition, and in this study the physician's current diagnosis of a biologic false-positive reaction would have been in error 38 percent of the time. On the other hand, as shown in table 3, regardless of the physician's opinion of present status of the patient, 72 percent of the serum specimens from 370 patients with histories of past syphilitic infections gave reactive results in the TPI test. The remaining 28 percent produced nonreactive results and were in disagreement with a previ-

about the present condition of the patient in terms of probable syphilitic infection. The bases for medical opinions were probably not constant since the 2,875 specimens were submitted by several hundred physicians through more than 50 State and Territorial laboratories.

Criteria for Acceptance

Criteria for acceptance in the TPI testing service required that the specimen be obtained from either diagnostic problem patients with no history or clinical evidence of syphilis or patients with suggestive evidence of syphilitic infection who had not received treatment; that neither the blood nor serum be exposed to rubber stoppers; and that a sterile serum sample be prepared by the State or Territorial health department laboratory and submitted with a completed clinical data sheet in the same mailing container to the Venereal Disease Research Laboratory. Specimens received directly from physicians were returned without testing. Reports of TPI test results were returned only to the submitting laboratory for subsequent forwarding to the originating source. The Venereal Disease Research Laboratory has furnished guide forms explaining these requirements, together with clinical data sheets, to the State public health laboratories for distribution to physicians.

Valid results were obtained with the TPI test on 2,465 serum specimens (table 1). The terms "reactive," "weakly reactive," and "nonreactive" are used instead of "positive," "weakly positive," or "doubtful," and "negative," in accordance with the 1953 recommendations of the National Serology Advisory Council to the Surgeon General of the Public Health Service.

Table 2 summarizes the findings for all of the 2,652 specimens which were included in this study.

All patients whose serum produced an inconclusive result in this test were treated with penicillinase and the serums were retested. The low percentage of inconclusive reports (less than 1 percent) was attributed to the use of paraffin-coated cork-stoppered tubes (7) instead of the rubber-stoppered tubes used in previous studies (8). Only 0.6 percent of the specimens were lost through leakage or breakage in transit. However 150 specimens, or almost 6 percent of the total, were grossly bacterially contaminated upon arrival and so were not tested. They were reported as "unsatisfactory for testing, due to bacterial contamination." Since adequate evidence regarding the possible effect of bacterial contamination of the serum on the TPI test result was not available, it was considered to be inadvisable to test grossly contaminated specimens.

As shown in table 1, approximately two-thirds of the specimens were from female patients. Since a request for a TPI test probably indicates some doubt as to syphilitic infection, these figures indicate that diagnostic problems occurred more frequently in females.

For the serum specimens which produced valid TPI test results, the percentage of positive findings (reactive plus weakly reactive) was lower for female donors (41.7 percent) than for male donors (52.4 percent). If TPI test negativity is taken as an index of false-positive reactions in other tests for syphilis, then these findings indicate a higher percentage of biologic false-positive reactors among female patients than was encountered among the male patients in this selected group. It

Table 1. Results of TPI tests on 2,465 serums submitted to the Venereal Disease Research Laboratory by State and Territorial health department laboratories, January 1–December 31, 1955

| Test result | Male | | Female | | Total | |
|----------------------|--------|---------|--------|---------|--------|---------|

Vending Machine Sanitation

The changing character of the vending machine industry has given rise to new needs for sanitation. These needs, as well as current research and control efforts, were treated in panel discussions at the Regional Educational Conference of the National Association of Sanitarians in Atlantic City on November 11, 1956. The following are highlights from the panel presentations of Arthur J. Nolan, Dr. Walter L. Mallmann, and William C. Miller, Jr.

Sanitary Control Criteria

brief Coin machine sales of products and services, exclusive of music and games, amounted to approximately \$2 billion in 1956. More than 45 classes of products were sold, from aspirin to tissues, and including numerous items of food and drink. Typical service vending machines are coin changers, washing machines, toilet locks, and mechanical ponies.

The kinds and numbers of coin machines, particularly those dispensing food, have increased sharply each year.

To illustrate the scope of the industry, here are some statistics from the January 1956 *Vend*

By Arthur J. Nolan, M. S., vice president, research and development, Dixie Cup Co., Easton, Pa., and chairman of the National Automatic Merchandising Association Sanitation Committee.

Magazine census covering product vending machines on location:

| | <i>Units</i> |
|---------------------------------------|--------------|
| Confection and package goods..... | 1,500,000 |
| Cigarettes and cigars..... | 600,000 |
| Bottle drinks..... | 650,000 |
| Cup drinks, cold..... | 75,000 |
| Cup drinks, hot..... | 75,000 |
| Ice cream and frozen confections..... | 30,000 |
| Packaged and bulk milk..... | 30,000 |
| Miscellaneous other products..... | 200,000 |
| Total | 3,160,000 |

The rapid expansion of the vending machine industry after World War II brought to the fore a number of questions in the area of sanitation and public health.

There had been no recognition of the food and drink vending machines as such. Health jurisdictions were somewhat at a loss about how to interpret existing ordinances. Too often these had been set up for restaurants or food establishments, and chain stores, and the

ous diagnosis of syphilis made some time in the patient's past. Of those 295 specimens accompanied by a current diagnosis of syphilis, 92, or 31 percent, failed to react in the TPI test. The percentage of disagreement between a diagnosis of syphilis and the TPI test result was approximately the same, regardless of when the diagnosis was made.

In the biologic false-positive diagnosis category, 60 percent agreement with the TPI test was obtained. Overall correlation between the physician's present clinical opinion and the TPI test was approximately 61 percent.

Summary

1. Modifications of the original Nelson and Mayer method for performance of the *Treponema pallidum* immobilization (TPI) test adopted by the Venereal Disease Research Laboratory have made it possible to perform this test as a daily operating, routine laboratory procedure.

2. During a 1-year period of a nationwide TPI testing service offered to State and Territorial public health laboratories, more than 2,800 serums from diagnostic problem cases in syphilis were submitted for testing.

3. TPI test findings were considered in relation to the sex of patients, evidence of syphilitic infection, past or present, and the clinical opinions of the physicians submitting specimens for testing.

Senior Research Fellowships

Applications for senior research fellowships may be filed with the Public Health Service until September 1, 1957. Awards will be made about December 1, 1957.

This program is designed to attract and to hold able investigators in the basic sciences in the preclinical departments of medical schools, dental schools, and schools of public health. These fellowships are awarded for 5 years and are renewable.

No stipend ceiling is established by the Public Health Service for the senior research fellowship. The university is to request the amount it considers most appropriate.

Address requests for information and application blanks to the Chief, Research Fellowships Branch, Division of Research Grants, National Institutes of Health, Public Health Service, Bethesda 14, Md.

tion of fresh products to residuals is not condoned because bacteria in the residuals may contaminate the fresh product, with possibly hazardous consequences.

Where readily perishable products, such as milk and cream, are dispensed, delivery tubes, valves, containers, and any other surfaces in contact with the ingredients or the finished product should be cleaned and sanitized at a central commissary. Research finds that microorganisms grow rapidly in such equipment unless it is cleaned and sanitized each time it is serviced.

The storage of soups and stews at a temperature of 150° F., or above, is a novel method of dispensing food. We have little information on long-time storage of foods at high temperature even in the area of "commercially sterile" canned products. Tests on canned products indicate little, if any, deterioration in quality after a reasonable period of storage.

Each new development in automatic dispensing of food brings new needs for research. Research to date indicates that the developments in coin-vended food are largely sound and that the food vended is sanitary.

Ordinance and Code

brief

Initially, food products sold in coin-operated vending machines were nonperishable or semiperishable, but the range of such foods has broadened in recent years to include many foods and beverages of a readily perishable nature. This transition introduced new problems of food protection not normally encountered in conventional food service operations.

As the vending of perishable food expanded, many States and communities requested the Public Health Service to develop criteria for sanitary control of machine-vended foods. The National Automatic Merchandising Association also asked the Service to develop a

Poisoning From Vending Machine Drinks

The Los Angeles Health Department reported that two persons experienced nausea and vomiting within 15 minutes after drinking from a bulk vending machine. Investigators found that a defective carbonator valve permitted carbon dioxide to back up into a copper waterline. Chemical analysis of water from the carbonator indicated 260 p.p.m. of copper.

model sanitation ordinance and code for vending machines as a guide for interested State and local health jurisdictions and for industry. They felt that uniform sanitation standards, similar to those developed by the Public Health Service for the sanitation of restaurants and market milk, were essential.

In 1954 the Service initiated field studies of current vending machine design, fabrication, and operation. Problems encountered were discussed in detail with State and local food sanitation authorities and representatives of the vending industry. Conferences were also held with groups and individuals connected with research in vending machine operations.

One of the first steps was a review of State and local regulations specifically directed to the sanitary control of vending machine operations. In 1954 only six local health departments reported adoption of such regulations, but many recognized the need for sanitary control of food vending. The most comprehensive standards reviewed at that time were those developed for the Armed Forces by the Subcommittee on Food Supply, Committee on Sanitary Engineering and Environment, National Research Council. Although designed for bulk-type machines vending carbonated beverages into single-service containers, the general criteria proposed in these suggested standards appeared applicable to many other vending machine operations. Industry also felt that these criteria could be applied practically.

Upon the conclusion of background preparation, the actual drafting of a proposed ordinance and code began in 1955. After a working draft was completed and discussed with industry, the second working draft was submitted in April

By William C. Miller, Jr., chief, Food Sanitation Section, Milk and Food Program, Division of Sanitary Engineering Services, Public Health Service.

special problems connected with unattended automatic vending machines were not contemplated.

At the National Sanitation Foundation meeting in 1947, a vending machine clinic initiated a program for research and standards in sanitation. The clinic was attended by manufacturers, suppliers, sanitarians, and by representatives of other public health groups. The program has continued from 1948 to the present. Research problems are referred to Dr. Walter L. Mallmann at Michigan State College.

The Public Health Service is drafting a model code and ordinance for food and drink vending machines. Concurrently, the National Automatic Merchandising Association committee is completing negotiations at several universities with public health schools and adequate laboratory facilities to test and inspect various types of vending machines against the standards proposed in the model code and ordinance. Additional standards, as needed, will be developed by a joint committee of industry and public health.

This committee of industry, military, and public health representatives, including Public Health Service officials, is being formed to evaluate the testing and continuing research programs. Representatives have been appointed by industry and by such organizations as the International Association of Milk and Food Sanitarians, the National Association of Sanitarians, and the American Public Health Association. They will meet shortly to examine the proposed program and protocol.

Microbiological Research

brief What differences in health and spoilage aspects are presented by coin-vended food and beverages that are not exhibited in manually dispensed products? Offhand, I think of two. Vended products are unique in that there are no

By Walter L. Mallmann, Ph.D., professor of bacteriology, department of microbiology and public health, Michigan State University of Agriculture and Applied Sciences, East Lansing.

personnel to supervise delivery of the product to the consumer. And then, the location of the coin machine may be in surroundings that definitely are objectionable for open-food dispensing.

The objective of research on vended food and beverages is to determine the minimum conditions under which they can be dispensed without adversely affecting health. Despite extensive research in food sanitation, the plan of robot vending introduces numerous problems of machine design and operation. The mechanical device has no power to differentiate between satisfactory and unsatisfactory products. The machine must be designed to prevent contamination by the environment or by the user and to maintain the food properly between servicings.

Although some research has been done on the various types of machines and products, much more information is needed on protection against health hazards, effect of contact surfaces on the product and the consumer, storage life of the product, temperature of storage, and kinds of spoilage encountered in vended products. So far, tests have been made on dispensers of carbonated beverages, fruit juice, milk, dry and liquid coffee, dry and liquid soup, sandwiches and salads stored at 50° F. or less and canned and commissary-prepared foods stored at 150° F.

My own work on carbonated beverages indicates that the sirups are relatively resistant to microbial decomposition because pH is low, sugar content is high, and sodium benzoate has been added. Storage of sirups under carbon dioxide atmospheres or at temperatures of 50° F. or less prevents mold. To lessen the introduction of microbial contaminants, all storage tanks, sirup lines, mixing valves, and other contact surfaces should be readily removable, easily disassembled, and easily cleaned. Obviously, the machine should be designed for protection against insects, rodents, and dust.

This holds for the general sanitary design of all coin-operated machines handling food products regardless of the degree of perishability.

Frequent cleaning and sanitizing is recommended for machines dispensing fruit juices, liquid soup concentrates, chocolate sirup, and other readily perishable products. The addi-

Public Health in a Nursing School

By ROBERT E. COKER, Jr., M.D., M.P.H., FRANCES E. HART, R.N., M.P.H.,
and DORIS GOSNELL, R.N., M.Litt.

MANY PEOPLE, both those concerned with public health nursing and those concerned with nursing education, have long felt that the curriculums of most 3-year schools of nursing leave a great deal to be desired concerning the community aspects of health and disease. In many schools of nursing the curriculum includes little or nothing concerning either the family aspects of illness or community health agencies other than the hospital and its staff.

In Butler County, Pa., the faculty of a 3-year school of nursing and the staff of the county health department are working together to integrate public health into the curriculum of the nursing school.

Background

The Butler County Memorial Hospital, established in 1896, was expanded in 1954 from approximately 200 beds to 300 beds. It is the only general hospital resource in Butler County, which has a population of approximately 103,000. The school of nursing was established in 1903.

The Butler County Health Department was established January 1, 1954, as the first county health department in Pennsylvania. In 1952,

Dr. Coker, formerly director of the Butler County Health Department, Butler, Pa., is director, study of choice of specialties in medicine, and research professor, public health administration, School of Public Health, University of North Carolina, Chapel Hill, N. C. Miss Hart is director of nursing, Butler County Health Department, and Miss Gosnell is assistant director in charge of education, Butler County Memorial Hospital School of Nursing.

in anticipation of the establishment of the county health department, the Pennsylvania Department of Health had assigned public health personnel to Butler County. These personnel functioned as a State-administered local health district until the establishment of the county health department. The personnel of the State unit included a medical director, public health nurses, sanitarians, and clerical workers. After the formation of the county health department, the public health nursing staff was increased, additional sanitarians were employed, and a public health engineer and a public health educator were added to the staff.

During the 2 years from 1952 to 1954, while the public health program in the county was State-administered, the public health nursing staff and the faculty of the hospital's school of nursing began to work closely together. The faculty of the nursing school invited the director of public health nursing and staff nurses to participate in the instructional program of the school. The invitation was eagerly accepted. As the two groups worked together, each group became convinced that the curriculum of the school could be greatly enriched and the experience of the students could be greatly broadened by incorporating into the curriculum a community approach to health and disease.

In 1954, after a series of conferences between health department personnel and the nursing school faculty, it was concluded that experiences in community health for the nursing students could be incorporated into the curriculum. The administration of the hospital authorized the educational director and the medical-surgical instructor of the nursing school to

1956 for review and comment by all States, a representative number of communities, Federal agencies, the vending machine industry, and interested groups and individuals. Comments received are now under careful study for incorporation into the prepublication draft.

The format of the working draft resembles that in other recommended milk and food ordinances and codes developed by the Public Health Service: The ordinance provisions are followed by code material which details conditions of satisfactory compliance.

Sanitation provisions for vending machine operations are in section V of the proposed ordinance. This section is divided into seven parts. Part I deals with the source, wholesomeness, and protection of the food, beverage, and ingredients; refrigeration and warm storage of food; cleaning and bactericidal treatment of food contact surfaces; and protection of single-service containers. Part II relates to machine

location, and part III, exterior construction and machine maintenance. Part IV establishes construction and design criteria for both food contact and nonfood contact surfaces. Parts V and VI deal with water supply and waste disposal, and part VII contains provisions concerning the delivery of foods, ingredients, equipment, and supplies to the machine location.

The other sections relate to administrative procedures, disease control, and enforcement considerations.

Since the vending of readily perishable foods and beverages are the major public health problem, most of the ordinance provisions are concerned with the protection of these products. However, the ordinance itself covers all types of food and beverage vending machines.

Following a review of the prepublication draft of the ordinance with representatives of both official agencies and industry, the document will be published.

Emergency Health Service Training

Training in numerous phases of emergency health services is available to professional medical and health personnel on a nationwide scale.

The training covers public health activities in national emergencies, epidemiology, advanced training for sanitary engineers, public health nursing, operation of emergency water supply equipment, radiological monitoring, detection and control of radioactive pollutants in water, organization of communicable disease control programs, and active duty under actual emergency conditions.

Confined principally to officers in the Public Health Service's Commissioned Reserve, the training is made available either by attendance on active duty or through correspondence courses. Commissioned Reserve officers are professional medical and health workers who serve on active duty primarily in times of

national emergency and during training periods.

Courses are held regularly in Public Health Service facilities in Atlanta, Cincinnati, San Francisco, and Washington, D. C. Other courses are given by the Federal Civil Defense Administration in Battle Creek, Mich., by the Industrial College of the Armed Forces in Washington, D. C., or in association with local health agencies.

The Commissioned Reserve is open to physicians, nurses, dentists, sanitary engineers, pharmacists, veterinarians, psychologists, bacteriologists, microbiologists, medical record librarians, statisticians, health educators, medical and psychiatric social service workers, and other professional personnel actively engaged in preventive medicine and public health practice.

on home visits. In some instances, these visits were made to patients who had been discharged from the hospital, and the student observed how the public health nurse conducted health teaching in the home. In other instances, an attempt was made to provide observation home visits to types of cases which the student was not likely to see in the hospital.

Following these home visits, the student nurse reported her experiences to the class. The public health nurse helped the student with the preparation of these case studies, and a member of the staff of the health department attended the class presentations and case discussions.

This concluded the experiences of the first year in the integration of public health into the nursing school curriculum.

Results of First Year

At the end of the first year a meeting was held with the hospital administration, the advisory board of the school of nursing, the faculty of the school, and the personnel of the health department to evaluate the year's experience. This evaluation emphasized the following points:

- The reaction of the head nurses and supervisors who had spent a 2 weeks' orientation period in the health department was universally enthusiastic. Their consensus was that they had had a rich learning experience. Not only did they feel that the instructional program for student nurses had been enhanced but that they themselves were able to provide a higher quality of nursing service than formerly. They had developed a greater awareness of the hospital patient as a member of a family and of a community and of the community resources available to meet individual and family health needs.

- The faculty of the school felt that the interest, response, and motivation of the student nurses was very gratifying. The students, too, had developed a concept of the relationship of health and disease in individuals to family and community problems, a concept which previous classes had not developed. Their interest in the patients with whom they worked had been increased by seeing them in the frame of reference of the family and the community.

Vol. 72, No. 4, April 1957

- The number of referrals of hospital patients to the public health nursing service had been greatly increased. This was particularly apparent in the areas of maternal and child health and adult health or chronic disease, fields in which the health department was anxious to expand its activities. Referrals to each of these public health nursing services more than doubled. The quality of referrals also greatly improved in the sense that cases selected for referral were increasingly those for which public health nursing might be expected to provide help. This was partly the result of the desire of the hospital staff to provide additional teaching materials for the student nurses in the form of more patients for them to visit with public health nurses. But it was also felt that the increase in the number and quality of referrals resulted in large measure from the increased sensitiveness of the head nurses and supervisors to patient needs and to the potentialities of public health nursing.

- The reaction of the medical staff of the hospital to the program was excellent. In many instances, they had become aware of and made use of community resources which they had not before appreciated or used. This was reflected in part by an increase of more than 20 percent in referrals by physicians to the public health nursing service.

Extension to Third-Year Curriculum

With the gratifying results of this experience during the nursing students' first year, a plan was developed to incorporate the community aspects of nursing into the remainder of the curriculum. Since the students spend most of their time away from the local hospital in other affiliated institutions during their second year, attention was directed to the third year of the nursing course.

During this year, the first approach to the integration of public health into the nursing school curriculum was made through the students' experience in obstetrical nursing. The existing system of referrals of obstetrical patients to the public health nursing service from the practicing obstetricians and from the hospital obstetrical service made this integration easier. Here again, the first step was to

work with the medical director and director of nursing of the county health department to plan and organize such a revision of the curriculum.

First-Year Curriculum

The purpose of the curriculum revision was defined as "to enrich the student nurses' program of study by the integration of principles of public health and the social aspects of nursing into the total plan of instruction." Under this purpose, health department personnel planned with the faculty of the school of nursing to accomplish the following objectives:

- To provide experience for students in the team approach to problem solving.
- To demonstrate to students social and health problems of families in the home.
- To review course outlines and to provide instructors with teaching materials, references, and public health information in all areas where these could be adapted to the course.
- To set up in the course on sociology special health centered projects for students.
- To demonstrate home nursing visits to students using discharged patients with whom the student had worked in the hospital.
- To assist students in preparing case studies and in participating in class and ward discussions.
- To demonstrate the importance of continuity of patient care, social and emotional factors in relation to health and disease, and the role of the nurse in understanding the patient as an individual in relation to his family and the community.

After these objectives had been set, it was agreed that they could not be met unless the teaching personnel of the school, the hospital supervisors, and the head nurses themselves understood the objectives and had participated in the experiences which the students would be undergoing. Therefore, with the approval of the hospital administration, administrative supervisors, head nurses, and nursing school faculty who had not had previous public health experiences were each assigned to the health department full time for 2 weeks. This experience acquainted them with the health department, with community health problems,

and with the organizations, agencies, and community resources working with these problems.

While this program of experience for the instructional personnel was in process, detailed planning of the curriculum for the students was carried on. It was agreed that students should be introduced to the health department during their first week in school and even before their orientation to the various divisions of hospital nursing. This introduction was provided by a class visit to the health department, during which the work of the department and its relationship to community health programs were discussed by the medical director, director of public health nurses, director of environmental health, and public health educator.

The health educator then introduced the students to group discussion methods. A series of discussions was held, with the class divided into small groups. These discussions had the dual purpose of further developing the students' concept of community health and of providing an opportunity for them to develop skills in group discussion methods, skills which would be useful to them later in ward conferences and case discussions following visits to families in their homes.

During the course entitled "Introduction to the Medical Sciences," arrangements were made for each student nurse to spend a half day with a public health nurse visiting families in their homes. Observation experience in environmental health was also provided by having students spend another half day in field work with health department sanitarians. The course instructor prepared the way for these visits by advance discussion with the class and by providing a written guide for the student nurses to use in making observations. It was hoped that these visits would give the student some conception of what illness means to the family and the community as well as to the patient.

The next step in the program was to integrate public health into the course in "Medical-Surgical Nursing." The course instructor presented disease entities as community problems, and students studied some of the ways in which illness affects the community and ways in which community problems affect illness. Here again, in carefully selected cases, the student nurse accompanied the public health nurse

The general principles of neutron activation analysis and the availability of this service suggest that the method may be of value to public health workers.

Neutron Activation Analysis

By MORGAN S. SEAL, M.S., WILLIAM A. MILLS, M.S., and
JAMES G. TERRILL, Jr., C.E., M.B.

PUBLIC HEALTH laboratories may in the near future put to use a nucleonic method of identifying and measuring trace quantities of elements. In essence, the process consists of exposing a sample of the material to be analyzed to neutrons in a reactor. The elements in the sample thereby become radioactive and their radiations provide the key to their character and abundance. In most instances, this service may be obtained through contract with reactor operators.

The detection and quantitative estimation of trace quantities of metallic contaminants in such materials as water, milk, food, insecticides, and construction materials have always presented problems to the public health analyst. The magnitude of these problems depends on the specificity and sensitivity of standard analytical procedures available for each individual contaminant and, to a certain extent, on the medium in which the contaminant is found.

Recent developments in electrometric, spectrophotometric, and spectrographic techniques

Mr. Seal is a chemist and Mr. Mills is a physicist with the Radiological Health Program, Division of Sanitary Engineering Services, Public Health Service. Mr. Terrill is chief of the program.

G. W. Leddicotte, chief of the activation analysis group at the Oak Ridge National Laboratory, and his staff assisted the authors in making a study of the neutron activation method of analysis. They contributed their time, facilities, materials, and knowledge.

have greatly increased the number of methods available to the chemical analyst and, in addition, because of the greater specificity of the new techniques, have shortened the time and reduced the labor required for most of the classic gravimetric and volumetric analytical procedures. Continued application of instrumental methods of analysis by public health workers should be encouraged through the development of applied research programs designed to solve specific public health problems. At the same time, public health personnel may want to consider the possibilities of using neutron activation analysis.

The theory of chemical analysis by the identification of characteristic radiations emitted by a particular nuclear species was advanced soon after the discovery of artificial radioactivity, and the technique was first applied to the solution of analytical problems in 1936 (1). Before the development of the nuclear reactor, however, these analyses necessitated the use of particle accelerators or other sources of highly energetic, charged nuclear particles. The scope of such analyses was necessarily limited by the low particle beam intensities.

In theory, any nuclear reaction producing a radioactive isotope that may be identified by its characteristic radiation can be used for activation analysis. However, the most useful reaction involves the capture of a neutron by a stable nucleus to produce a radioisotope of the original atom. The radioisotope formed will have a characteristic nuclear emission of a par-

provide the obstetrics instructor with an opportunity for field observation and experience with the health department. This experience included accompanying the public health nurse on home visits to patients receiving prenatal and postpartum care.

The experience of the student nurses also included visits to prenatal patients whom they would later see in the hospital on the obstetrical service, and visits in the home to mothers and babies whom they had cared for in the hospital. These visits were followed by case studies and class discussions, with health department staff participating. In preparation for the observation home visits with the public health nurse, the instructor provided the students with a written guide such as had been provided the first year students.

The students also participated in teaching classes of prospective parents, which are held on a continuing basis by the health department in cooperation with the nursing and medical staff of the hospital.

This is the extent to which the integration of public health into the curriculum of the Butler County Memorial Hospital School of Nursing has proceeded. It is the hope of both health department staff and nursing school faculty that this integration can proceed much further and that the participation of the health department in the instructional program of the nursing school can be expanded. An outpatient department will be developed in the hospital within the near future, and it is planned to take advantage of the opportunity which expanded clinical services will provide for instruction in community health.

Both the hospital and the health department feel that their effectiveness as community health agencies has been greatly improved. The hospital is producing graduate nurses who have a better concept of community health needs and resources. At the same time, patient care has

in many instances been improved by continuity of care between home and hospital. The health department has been able to expand services in certain areas of community need and its service to individual families has been improved by the close relationship to the hospital nursing staff. This is, however, a demanding program on health department staff. It is time-consuming and at times disruptive of service program organization. Nevertheless, it is felt that the ultimate contribution to community health is well worth the time and effort.

Summary

An experience in the integration of public health into the curriculum of a 3-year school of nursing has been described. Through the cooperative efforts of the Butler County [Pa.] Health Department and the faculty of the Butler County Memorial Hospital School of Nursing, with the sanction and support of the hospital administration, a plan was developed and carried out for providing student nurses with experiences in the community aspects of health and disease. This began with providing 2 weeks of full-time experience in the health department for hospital supervisors and head nurses. The nursing students' experiences included introduction to community health agencies, observation field visits with public health nurses and other health department staff, demonstrations in the continuity of medical and nursing care both before and after the patient's hospital stay, and case studies and discussions. These experiences were accompanied by a review of the curriculum and the planning of individual courses in such a way as to emphasize the interrelationships between individual patients, the family, and the community. Although this is a time-consuming program for the health department staff, it is believed that it pays substantial dividends in improved nursing service for the community.

or the ratio of the amount of activity produced in time t to that produced in infinite time. The half-life ($T_{1/2}$) is determined experimentally for each isotope. It may be obtained or calculated from any compilation of nuclear data, such as the Seaborg tables (3).

The actual irradiation is carried out in a nuclear reactor at a point where the desired neutron intensity (flux) is available. The neutron flux need not be constant, since both the unknown and the standard are subjected to the same flux during the same length of time. The sample is allowed to remain in the reactor until the desired amount of radioactivity is obtained, as calculated from the above equation. After this length of time, the container is removed from the reactor, and the samples are prepared for radiochemical separation, due precaution being observed to protect the worker from radiation exposure.

No specific instructions can be given for the preparation of the sample for radiochemical analysis, except to state that the sample must be put into solution. Procedures vary with such substances as plant material, animal tissue, and other matter. Care must be taken to prevent the loss of easily volatilized radioelements if they are being determined. Dissolution of the standard should present no problem since the standard selected will be readily soluble.

The validity of a radiochemical analysis depends on the fact that radioactive atoms behave exactly the same way chemically as nonradioactive atoms of the same element. Although a large amount of radiation may appear in a particular sample, the actual weight of radioactive material present is extremely minute, often being in the order of 10^{-10} gm., or even less. For this reason, it is usually necessary to add to the dissolved unknown measured quantities of pure, standardized, nonradioactive solutions of the element being determined. Such materials are known as carriers, since the relatively few radioactive atoms are carried with the milligram quantities of nonradioactive material throughout the radiochemical analysis. Recovery of the total amount of carrier in the final weighing form need not be quantitative, but it should be in the order of 60 percent or better.

The procedure for chemical analysis depends on the element being determined. Kahn has

prepared abstracts of unclassified radiochemical methods that cover the literature through 1953 (4). In addition, members of the Analytical Chemistry Division of the Oak Ridge National Laboratory are preparing an unclassified "master manual" of radiochemical techniques.

An Example: Copper Determination

To obtain more information on activation analysis, the authors, with the assistance of G. W. Leddicotte and the activation analysis group at the Oak Ridge National Laboratory, carried out three separate analyses: the determination of copper in a nickel oxide sample, the determination of copper in an animal tissue sample, and the determination of sodium in a cast iron sample. We selected these analyses because they present examples of a contaminant in both organic and inorganic materials and because they illustrate the differences between elements. Details of the experiment are given only for the determination of copper in nickel oxide.

Irradiation and Chemical Analysis

Triplicate 100-mg. samples of nickel oxide and a single 20-mg. sample of pure copper metal were irradiated for 16 hours in the Oak Ridge National Laboratory's graphite reactor. Neutron flux at the point of irradiation equaled about 6.50×10^{14} neutrons per cm.² per second.

To separate the copper from the other elements, we followed the procedure set down by the laboratory's Analytical Chemistry Division, as given below:

1. To the acid solution of the irradiated sample, add standardized copper carrier and the following holdback carriers: iron, cobalt, zinc, manganese, cadmium, strontium, and sodium.

2. Adjust the solution to 1N HCl, saturate with sodium sulfide, centrifuge, and discard supernate. Wash precipitate with two 10-ml. portions of hot water. Centrifuge and discard washes.

3. Dissolve the precipitate in 1 ml. of concentrated HNO₃ containing BrO₃, dilute to 10 ml. with H₂O, and add Fe holdback carrier. Make basic with 6N NH₄OH, and centrifuge out Fe(OH)₃. Add additional Fe holdback carrier, and centrifuge down on top of first Fe(OH)₃ precipitate. Discard precipitate.

ticular energy or energies. In the most frequently used type of reaction, the nuclear emission is a gamma (γ) ray, and reactions of this type are commonly designated as (n,γ) reactions. A generalized reaction of the (n,γ) type is:

In this reaction, the elemental isotope (X) is bombarded by a neutron (n), resulting in a radioactive isotope of the element (X) and an instantaneous gamma ray (γ). Decay of the radioactive isotope may result in a characteristic gamma ray. It is the characteristic gamma ray of the radioactive isotope that is of importance in this method, not the gamma from the (n,γ) reaction.

Modern radiation-detection instruments are capable of detecting gamma radiation of a particular energy and of differentiating it from gamma radiations of other energies. The amount of gamma activity is dependent on the quantity of radioactive nuclei present. In addition, each radioisotope decays at a constant rate. By observing the amount of gamma activity at two or more suitable time intervals, the decay rate may be ascertained. These quantities, the energy and the decay rate, are normally sufficient to determine exactly what nuclear species are present; the activity then determines the number of radioactive atoms present.

Neutron activation analysis has been carried out on an ever-increasing scale at the Oak Ridge National Laboratory since 1943. Since it is not the purpose of this paper to review the theory or the history of neutron activation analysis, the reader is referred for this information to the excellent unclassified report entitled "Neutron Activation Analysis" by Leddicotte and Reynolds (2).

General Procedure

The sample containing the contaminant may be either a solid or a solution. In either case, a known amount by weight or by volume is placed in a suitable container for insertion in a nuclear reactor. A pure weighed sample (analytical reagent grade will usually suffice) of the element to be determined, known as the standard,

is also placed in the container, as close to the unknown as possible. The container is usually made either of quartz or aluminum, substances which do not shield the samples from the neutron field and which do not in themselves present an excessive radiation hazard after neutron bombardment. For the sake of accuracy, two or more samples of both the unknown and the standard are prepared.

The standard may be either the element itself, as is the case with copper determinations, or a stable compound, such as Na_2CO_3 for sodium determinations. The use of a thermally stable chemical form of the standard is important, since the samples are often subjected to considerable heat. More important, however, it is desirable for safety reasons that the elements in the standard other than the element being determined not form intensely radioactive isotopes.

The size of the samples and standards depends on the rate of formation of the radioisotope in a particular neutron field. The rate of formation may be calculated from the rate of decay, which, as stated above, is a constant for a particular radioisotope. In addition, the known intensity of the neutron field and the probability that a particular atom will capture a neutron enter into the calculation. The probability that a certain reaction between a nucleus and an incident particle or photon will occur is known as the nuclear cross section of the atom. These factors may be summarized in the following equation:

$$W = \frac{AM}{6.02 \times 10^{23} f \sigma S}$$

where

W = weight of the element

A = activity of disintegrations per second

M = chemical atomic weight

6.02×10^{23} = Avogadro's number

f = neutron intensity (flux) per cm^2 per second

σ = probability of neutron capture (cross section) in cm^2

S = saturation factor

The factor S warrants further explanation.

$$S = 1 - e^{-\frac{0.693t}{T_{1/2}}}$$

tion of the positive electron (positron) and the emission of the rare-occurring (0.5 percent) 1.34-Mev. gamma from the Cu^{64} isotope. When a positron emitter decays, the positron and an electron will collide, annihilate their masses, and produce, usually, two gammas of 0.51 Mev. each. (The energy associated with the rest mass of an electron or positron is 0.51 Mev.) The scintillation spectrometer was calibrated with a known source of Na^{22} , which is also a positron emitter, in addition to having a transition gamma. Figures 1, 2, and 3 show the results from the spectrometer. Since a gamma peak for all samples occurred at 0.51 Mev., the purity of the copper in the test samples was satisfactory.

Limitations

Like any other method of analysis, radioactivation analysis has its limitations. These limitations may be divided into three classes: physical, chemical, and nuclear (5).

Physical

1. A sample must be of such character as to withstand temperatures of possibly 70° C. to 90° C.

Figure 2. Cu^{64} spectrum: standard sample.

Figure 3. Cu^{64} spectrum: nickel oxide sample.

2. Containers must be constructed of materials that, when irradiated, have very short half-lives.

3. The size of the samples is limited by the irradiation space in a reactor.

Chemical

1. Samples may undergo structural changes as a result of high radiation intensities, and these changes may result in losses of radioactive material by volatilization.

2. Some limitations arise in separating the desired activity from other radioactive elements in the samples, the magnitude of these limitations depending on the number of steps in the radiochemical procedure used.

3. It is not always easy to treat the samples in such manner that the irradiated element and the carrier element will behave similarly chemically.

Nuclear

1. The samples must not have such a high neutron absorption as to affect the neutron flux throughout the samples.

2. A major limitation is that the isotope formed may be the result of neutron reactions other than an (n, γ) reaction.

3. Of some importance is the formation of radioisotopes of the same element differing from

Table 1. Results of copper determination

| Sample | Net weight (mg.) | Dilution | Separated CuCNS weight (mg.) | Percent yield ¹ | CCM ² (counts per minute) |
|-------------------|------------------|-------------------|------------------------------|----------------------------|--------------------------------------|
| Nickel-oxide..... | 52.4 | 1:1 | 19.1 | 40.3 | 41,032 |
| Nickel-oxide..... | 43.7 | 1:1 | 22.2 | 46.8 | 37,233 |
| Nickel-oxide..... | 46.2 | 1:1 | 27.1 | 57.2 | 43,443 |
| Standard..... | 41.0 | 1:10 ⁴ | 27.2 | 57.4 | 99,763 |
| Standard..... | 41.0 | 1:10 ⁴ | 21.9 | 46.2 | 79,581 |

¹ Theoretical yield of CuCNS was 47.4 mg.

² Count corrected for background and chemical yield.

4. Acidify with HCl to 0.5N in HCl. Add sodium bisulfite solution to reduce Cu^{++} to Cu^+ , and add solid KCNS until CuCNS precipitates; then add slight excess of KCNS. Centrifuge and wash precipitate with two 10-ml. portions of water.

5. Filter with suction through a tared filter paper. Wash with three 5-ml. portions of water and three 5-ml. portions of alcohol. Dry 15 minutes at 110° C. Weigh as CuCNS (1.92 mg. per mg. Cu). Mount and count.

Calculating the Quantity

After chemical separation, each sample was counted on a scintillation counter, using a thallium-activated sodium iodide crystal, an RCA 5819 photomultiplier, and an aluminium absorber for stopping soft beta rays. (Other equally suitable counting methods are available.) From the radioactivity in the standard

samples and that in the nickel oxide samples, the trace quantity of copper was determined. The data for the samples are given in table 1.

Calculations for the determination of copper were based on the following relationships:

$$\text{Percent chemical yield} = \frac{\text{weight of CuCNS recovered}}{\text{theoretical yield of CuCNS}} \times 100.$$

$$\text{Count corrected for background (CCB)} = \text{CCM} - \text{background per minute.}$$

$$\text{Count corrected for chemical yield (CCY)} = \frac{\text{CCB}}{\text{percent chemical yield}}$$

$$\text{CCY for unit weight of Cu in standard} = \frac{\text{CCY} \times \text{dilution}}{\text{weight of standard sample}}$$

$$\begin{aligned} &\text{Calculation of Cu in unknown sample:} \\ &\frac{\text{CCY for Cu in } X \text{ sample}}{(\text{weight of } X \text{ sample}) (\text{CCY for unit weight of Cu in standard})} \\ &= \text{number of grams of Cu in } X \text{ sample.} \end{aligned}$$

Results of the calculations gave an average value of 4.21×10^{-5} gm. Cu per gram of nickel oxide.

The purity of radioactive copper in the samples was checked in two ways.

First, we checked the radioactive half-life by re-counting each sample after an appropriate time interval. The decay agreed within 3 percent of the 12.8-hour half-life of the Cu^{64} isotope.

Second, we examined one of the standard samples and one of the unknown samples on a single-channel gamma ray scintillation spectrometer to measure the energies of the gamma rays emitted from Cu^{64} . The gamma rays measured were those resulting from annihila-

Figure 1. Calibration spectrum of Na^{22} 

Preliminary studies indicate that the RPCF test is comparable in sensitivity with the TPCF test. It compares favorably in specificity with the TPCF and TPI tests. The production of antigen for this test is relatively simple and inexpensive.

Reiter Protein Complement Fixation Test for Syphilis

By GEORGE R. CANNEFAX, B.S., and WARFIELD GARSON, M.D., M.P.H.

SUSPENSIONS of the Reiter strain of *Treponema pallidum* were first employed in the serodiagnosis of syphilis by Gaehtgens (1). He reported satisfactory sensitivity and specificity with a complement fixation test in which the suspension was used as antigen. Reports of the use of Gaehtgens' antigen in this country first confirmed (2-4) and then denied (5, 6) the specificity of the test. Subsequent investigations demonstrated a lipid substance of Reiter's organism which reacted with reagin, the serum substance which reacts with ubiquitous tissue lipid or cardiolipin antigens (7-9). It therefore appeared that a suspension of Reiter's treponeme produced false-positive reactions and possessed no advantage over the use of tissue lipid antigens.

In addition to the lipid antigen of Reiter's organism, D'Alessandro and co-workers demonstrated the isolation of a thermolabile soluble protein antigen (antigene treponemico proteico

solubile) from the Reiter strain of *T. pallidum* (9). It was demonstrated that the substance reacting with the protein antigen was not reagin. The protein antigen was found to be reactive with the serum of yaws and syphilis and with Reiter antiserum. It was therefore postulated that the protein antigen represented a group-specific substance.

This report presents the method used for the isolation of protein antigen from the Reiter strain of *T. pallidum* and preliminary observations on the use of the antigen in a complement fixation test descriptively designated as the Reiter protein complement fixation (RPCF) test. RPCF test results on 1,380 serum specimens (765 syphilitic and 615 presumably non-syphilitic) are compared with results obtained with the *Treponema pallidum* immobilization (TPI) test and the *Treponema pallidum* complement fixation (TPCF) test.

The following techniques were used in the study:

TPI test: Nelson and Diesendruck (10) with added complement according to Thompson and Magnuson (11) and increased sodium thioglycolate as recommended by Portnoy, Harris, and Olansky (12).

TPCF test: Original procedure of Portnoy and Magnuson (13).

RPCF test: Kolmer one-fifth volume technique (14) without modification except that Reiter protein antigen was used in place of Kolmer antigen.

Mr. Cannefax is a bacteriologist with the Public Health Service Venereal Disease Experimental Laboratory at the University of North Carolina School of Public Health, Chapel Hill, N. C. Dr. Garson is director of the laboratory and head of the department of experimental medicine. Technical assistance in the study was given by Mrs. Dorothy H. Houser and Mrs. Marie B. Nifong.

Table 2. Sensitivity comparison (micrograms per milliliter)

| Element | Reactor 5×10^{11} flux | Reactor 10^{12} flux | Copper spark | Graphite direct cur- rent arc | Flame spec- tropho- tometer | Sensitive color reaction | Ampro- metric titration |

| Selenium | .05 | .0025 | | | | | 200.0 |

the isotope under investigation as a result of the decay of other radioactive species. However, this limitation may be overcome by determining decay and energy of emission.

Comparison With Other Methods

Meinke (6) has compared activation analysis with other means of trace analysis for elements from hydrogen to uranium. His findings on a few elements of importance in drinking water standards are given in table 2. For all of these except iron and magnesium, neutron activation analysis at a thermal neutron flux of 10^{12} is more sensitive than any of the other trace methods considered.

Its Future in Public Health

We believe that activation analysis has a future in public health laboratory operations. Sensitivity of the method is increasing with the development of higher flux reactors. In fact, Meinke reports that many scientists feel that activation analysis will be the ultimate method of analysis. Its use, of course, depends on the availability of nuclear reactors.

We suggest that the reader become more familiar with the method through the references given (2, 5-8) and determine whether it is a possible solution to his problem. An activation analysis service is presently available at the Oak Ridge National Laboratory for a nominal charge to industrial, academic, and govern-

mental institutions. Samples are sent to G. W. Leddicotte, Analytical Chemistry Division, Oak Ridge National Laboratory, P. O. Box P, Oak Ridge, Tenn. Following analysis, the results are returned to the sender in terms of micrograms per gram, parts per million, or other usable units, as requested. Additional information may be obtained by writing to the above address.

the three tests, by stage of syphilis, is presented in table 2. The TPI test has the lowest percentage of positive results in cases of primary and secondary syphilis, 25.7 and 72.7, respectively, as compared with 62.9 and 89.7 for the TPCF test and 61.4 and 84.6 for the RPCF test. This difference, which is probably due to the fact that the TPI antibody appears later in the course of infection than do the other antibodies, accounts, in great measure, for the

generally lower sensitivity of the TPI test. When all diagnostic groups are combined, the positivity rates are 75.4 percent for the TPI test, 82.6 percent for the RPCF test, and 86.8 percent for the TPCF test.

The TPCF test had a 4.19 percent higher positivity than the RPCF test with this group of specimens. The difference in percentages was found to be of borderline significance when a normal deviate test of the percentage differ-

Preparation of Antigen

The Reiter strain of *T. pallidum* was grown in modified Brewer's fluid thioglycolate medium (A) which was gently agitated during incubation by means of a magnetic stirring device. The dehydrated medium was dissolved in distilled water, allowed to stand overnight at 6° to 8° C., and filtered through filter paper to remove agar. The medium was sterilized by autoclaving at 15 pounds' pressure for 30 minutes in a 4-liter aspirator bottle. Horse serum was added to make a final concentration of 10 percent prior to inoculating a 4-liter bottle with 200 ml. of a 3-day culture of Reiter treponemes. The cultures were incubated at 37° C. for 4 to 6 days. The organisms were collected by centrifugation in a refrigerated anglehead centrifuge at 4,000 r.p.m. The sediment of treponemes was evenly suspended in physiological saline solution and washed three times to remove medium components.

Extraction of Protein Antigen

The washed treponemes were suspended in physiological saline solution in the proportion of 1 gm. of moist weight of sediment to 20 ml. of saline solution. The suspension was placed in stainless steel centrifuge cups and rapidly frozen at -70° C. in a mixture of dry ice and alcohol. After complete freezing (5 minutes) the tubes were thawed with continuous agitation in a 37° C. water bath. After 15 freeze-thaw cycles the suspension was centrifuged in the cold at 10,000 r.p.m. for 1 hour. The residual sediment of treponemes was then resuspended in fresh saline solution in the proportion of 10 ml. for each gram of original moist weight of organisms. The whole procedure of cryolysis was repeated five times, making a total of 75 freeze-thaw cycles. The end product of cryolysis was approximately 60 ml. of opalescent fluid, which was placed in cellophane dialysis tubing.

Dialysis was started by placing the tube on a rotating device and suspending the tube in a 10 percent saturated ammonium sulfate solution (pH 7.2 to 7.4) at 6° to 8° C. for 8 hours. The ratio of ammonium sulfate solution to cryolysate was approximately 20 to 1. Every 8 hours the ammonium sulfate solution was re-

placed by one of 10 percent greater concentration until a 50 percent saturated ammonium sulfate solution was reached. Dialysis against the 50 percent saturated solution was allowed to continue overnight. The 50 percent saturated solution was replaced by one of 75 percent saturation and dialyzed for 8 hours. The 75 percent saturated solution was replaced by a fresh 75 percent saturated solution and dialysis was continued for another 8 hours. The dialysate was then transferred to a centrifuge tube and centrifuged at 10,000 r.p.m. for 30 minutes. The supernatant was removed and the protein, which had precipitated during dialysis, was dissolved in physiological saline solution in the proportion of 2 ml. of saline solution for each gram of original moist weight of treponemes. The protein solution was then dialyzed for 96 hours against physiological saline solution in the proportion of 2,000 ml. of saline solution for each 2 ml. of protein solution. It was then centrifuged for 30 minutes at 10,000 r.p.m. in an anglehead centrifuge in the cold. The supernatant, Reiter protein antigen, was stored in the refrigerator without preservative.

The method given for the preparation of Reiter protein antigen is the same as that of D'Alessandro and Dardanoni (15) except that the precipitate was put into solution and dialyzed against saline solution whereas phosphate buffer was used in the original method. Also, in the original method, merthiolate, 1:5,000, was added for preservation whereas here no preservative of any kind was included.

It should be noted at this point that, in lieu of the cultured source of organisms and the means of obtaining the protein fraction, the RPCF antigen is relatively simple to produce and quite inexpensive when compared with the antigens of treponemal tests currently in use.

Results

Table 1 shows results obtained by each test procedure on 765 serum specimens from patients diagnosed as having syphilis, by stage of disease. These data are summarized in tables 2 and 3.

The relative sensitivity (percent reactive) of

the complement titration methods were the same. The RPCF test would have been more sensitive had $1\frac{1}{2}$ exact units of complement been used in the test. It cannot be speculated what overall effect this would have had on the relative sensitivity or specificity of the RPCF test. This aspect of the test is the subject of further investigation.

The determination of specificity of one test in relation to other tests, in the absence of clinical information, is admittedly fallacious. It presupposes the 100 percent detection by the control tests of antibodies to syphilis infection. That this is not true is substantiated by an examination of the results of testing shown in table 2 in which patients with previous diagnoses of syphilis were found to be seronegative with both the TPI and TPCF tests. The occurrence of a positive reaction with one test and a negative reaction with another, with the same specimen, is, of course, a common observation in syphilis. This appears to be the case with at least 7 of the 10 presumably nonsyphilitic patients with positive RPCF test results on whom clinical information was obtained. The clinical status of the other 4 patients positive with the RPCF test and negative with both the TPI and TPCF tests has not been learned, and the possibility exists that some, or all, of these may have had previous diagnoses of syphilis. Therefore, it appears that the 98.86 percent specificity established in relation to the TPI and TPCF tests, with the specimens tested in this report, may represent the minimum rather than the maximum percentage of specificity of the RPCF test.

This preliminary investigation suggests that more intensive study and evaluation of the usefulness and limitations of Reiter protein antigen in the serology of the treponemal infections are indicated.

Conclusions

1. The RPCF test has, in this study, a relative specificity of 98.86 percent in comparison with the TPI and TPCF tests.

2. The RPCF and the TPCF tests appear to have similar percentages of overall sensitivity: TPCF test, 86.80 percent; RPCF test, 82.61 percent.

3. The RPCF test and the TPCF test detected, in this study, a higher percentage of primary and secondary syphilis cases than did the TPI test.

ences was applied. A normal deviate value of 1.96 is considered significant at the 5 percent level and a value of 2.28 was obtained. Statistically, these data do not present strong evidence of a greater general sensitivity with the TPCF test.

The relatively low positivity rate of the TPI test in primary syphilis is also reflected in table 3, which shows the percentage of agreement between the pairs of tests. In primary syphilis there was 81.4 percent agreement between the TPCF and RPCF tests, as opposed to 57.1 percent agreement between the TPI and TPCF tests and 58.6 percent agreement between the TPI and RPCF tests. In secondary syphilis there also appeared to be greater agreement between the TPCF and RPCF tests. The difference here, however, is not statistically significant nor are any of the differences observed following the secondary stage.

The 615 presumably nonsyphilitic serum specimens used for the determination of the relative specificity of the RPCF test were specimens which gave negative results to the TPI and TPCF tests in a serologic survey in an area with a high incidence of syphilis. Nothing was known of the clinical status of the patients at the time of the serologic survey or at the time of RPCF testing. Fourteen of the 615 specimens gave positive results in some degree with the RPCF test. This indicates a specificity of 97.72 percent in relation to the TPI and TPCF tests. Clinical information was subsequently obtained on 10 of these 14 patients. Seven had been previously diagnosed and treated for syphilis, and three denied

a past history of syphilis. Subtracting the seven patients with a previous diagnosis of syphilis, the specificity percentage becomes 98.86. Clinical information on the remaining four patients is not currently available.

Discussion

It has become a serologic axiom that tests employing Reiter's treponeme produce a high percentage of false-positive reactions. This preliminary investigation of a protein fraction of Reiter's organism (presumably free of lipid antigen substance which reacts with reagin) does not produce a high percentage of false-positive reactions when compared with the TPI and TPCF tests.

The only other investigation, to our knowledge, of a comparison of Reiter protein antigen with a specific test (TPI) is the work of J. H. de Bruijn of the National Institute of Public Health, Utrecht, Netherlands (16). His results with 116 syphilitic and 137 presumably nonsyphilitic serum specimens compare favorably with the results of this investigation.

The preliminary experimental data reported here, though not adequate for definitive evaluation, indicate that the RPCF test approximates, percentagewise, the degree of detection of syphilis, or relative sensitivity, afforded by the TPCF test. In relation to this comparison of sensitivity, it should be pointed out that the TPCF test and the RPCF test procedures were similar except that the TPCF test employed 1½ exact complement units whereas the RPCF test employed 2 exact complement units in which

THE

Philadelphia

HEALTH FAIR

What are the results achieved by a health fair? Pursuit of this question produced several findings which materially contributed to the effectiveness of subsequent fairs.

By JAMES P. DIXON, M.D., IRWIN M. ROSENSTOCK, Ph.D.,
JOHN B. DIBELER, M.P.H., and WILLIAM A. ALLEN, M.P.H.

PHILADELPHIA'S three health fairs, the first in 1954 and the latest in 1956, were the setting for an illuminating experience in the evaluation of health education techniques. This story about the effectiveness of the health fair in bringing community agencies together provides a valuable footnote to this experience.

Dr. Dixon is commissioner, Philadelphia Department of Public Health. Mr. Allen is director of the department's office of education, and Mr. Dibeler is director of education, Philadelphia division of the American Cancer Society. Dr. Rosenstock is assistant chief of the Behavioral Studies Section, Division of General Health Services, Public Health Service.

The Philadelphia Junior Chamber of Commerce invited official and voluntary agencies and professional societies to help plan the first health fair in Philadelphia and the first health fair in any large city. That was in 1952.

Early in 1954, when leadership and financing seemed certain, the Jaycees organized a steering committee, formed the nucleus of an executive committee, and appointed a treasurer and legal consultant.

The city department of public health, the health and welfare council, the board of public education, and county medical, dental, and nursing societies were among the agencies represented on the steering committee. The de-

PHS films

Collections of Specimens For Virus Studies

35 mm. filmstrip, color, sound, 9½ minutes, 58 frames, 1956.

Audience: Public health personnel, practicing physicians, clinical technicians.

Availability: Loan—Communicable Disease Center, Public Health Service, 50 7th Street NE., Atlanta 5, Ga. Purchase—United World Films, Inc., 1445 Park Avenue, New York 29, N. Y.

Methods of collection, preservation, and packing of specimens sent to the laboratory for virus diagnosis are explained in this filmstrip, which shows the type of specimens of

value and emphasizes the importance of timely collection.

Procedures for rapid preservation are demonstrated. Types of shipping containers are suggested and precautions in packing to insure against damage in transit are given. The film ends with emphasis on the necessity of sending complete data with the specimen.

Poultry Hygiene Series

Refrigeration Waste Disposal, Cleanup, and Basic Sanitation

35 mm., filmstrips, color, sound, 11 and 12 minutes and 39 and 72 frames, respectively, 1956.

Audience: State poultry inspectors and sanitarians, poultry plant supervisors and others concerned with the processing of poultry.

Availability: Loan—Communicable Disease Center, Public Health Service, 50 7th Street NE., Atlanta 5, Ga. Purchase—United World Films, Inc., 1445 Park Avenue, New York 29, N. Y.

Two more films of the poultry hygiene series have been released (see Pub. Health Rep. 71: 1080, November 1956). One depicts the essentials of waste collection, holding, and dis-

posal; the time and procedures for cleanup of processing rooms and equipment; and basic sanitation in the poultry processing plant and on the premises. The other film follows the processed bird through the plant to the retail market. It outlines the refrigeration temperatures and procedures during processing, storage, and transport.

near the main entrance, where it served as the center of administrative operations.

The publicity committee employed a local public relations agency to issue news releases to metropolitan and neighborhood newspapers, to write television and radio announcements, and to publicize news events related to the fair. News releases began several weeks before the fair, built to a high pitch at the opening, continued throughout the week of the event, and ended in a final roundup of pictures and stories.

The stage of the bandshell served as the focal point for the various programs, designed to draw attendance and entertain as well as to educate. A master of ceremonies announced programs, called attention to future demonstrations, and told the audience about the objectives of the fair and its sponsors. A nurse-of-the-year award, band concerts, pageants, and talks by the health commissioner, the presidents of the medical and dental societies, and other health authorities were included in the staged program.

Shortly after the fair, the agencies and committees evaluated the effectiveness of their own contributions and exchanged this information for use in planning the next year's fair.

Although planning of the second health fair represented an improvement over the initial efforts, committee members agreed that further improvement was desirable. Three weeks before the opening the executive committee requested assistance from the Public Health Service in planning an objective evaluation of the educational effectiveness of the fair. Committee members felt that the request should be made even though the time for planning was short. The Public Health Service agreed to help.

The community objectives for the 1955 fair were the same as those for the first fair. Obviously, any attempt to measure success in achieving these in a metropolitan area would face formidable obstacles.

Evaluation Process

In view of those obstacles, an attempt was made to evaluate progress by a method described in detail elsewhere (1). In brief, it

measures success with intermediate objectives that are importantly related to long-range objectives.

The short time available for planning imposed certain limitations on the evaluation. No evaluation of the long-range objectives was attempted even though certain of these might have been closer to realization than certain intermediate objectives; neither was there an attempt to measure the success of the fair in improving working relationships among the local health agencies, a result that seemed implicit in the production of the fair.

Accordingly, the executive committee agreed that evaluation would be confined to the following intermediate objectives:

1. For long-range objective *b*, noted above, the intermediate objective was to foster participation in the health tests planned for the fair.

2. For long-range objective *c*, the intermediate objective was to increase knowledge of community health services.

To evaluate success with these objectives, we interviewed persons entering and leaving the fair. Those interviewed on entering were not interviewed on leaving. Differences in knowledge between the two groups could be attributed to experience with the health fair. Through open-end questions, respondents would have an opportunity to discuss their impressions of the fair. In all, 215 adults were questioned on entrance and 202 on departure. The interviews, conducted by volunteers, students from Temple University, lasted 5 to 15 minutes.

The following summary lists the main points in the evaluation:

1. Nearly half (48 percent) of the fair visitors took at least 1 health test, and a fourth took 2 or more. No person took more than 4 tests.

2. In general, more men, more younger people, and more highly educated people visited the fair than would be expected on a purely random basis. Less well-educated people, older people, and, to some extent, women did not attend the fair in proportion to their numbers in the local population.

3. Evaluation of the fair objectives makes it clear that the long-range objectives were

cisions of this group were carried out by Jaycee and health agency co-chairmen of committees on arrangements, exhibits, program, publicity, and manpower. The fair was financed on a budget of \$10,300 by contributions from the participating agencies and the local Blue Cross.

The Health Education Committee of the Philadelphia Health and Welfare Council was an important catalyst in the initial planning. This committee, which included health educators from a number of local agencies, provided valuable aid in developing the fair as a communitywide activity in health education.

The fair had three major objectives for the public and three for the participating agencies.

For the public, the long-range objectives were (a) to create increased health consciousness through understanding of community and personal health problems, (b) to stimulate the practice of preventive medicine and periodic health examinations, and (c) to urge use of health services and other community facilities.

The immediate objectives for the participating agencies were to provide opportunities for cooperative effort in health promotion, for agency workers to meet the public face to face, and for health counseling. In addition, the agencies hoped that the publicity accompanying the fair would have educational significance beyond the fair itself.

Health fairs and health weeks, promoted by junior chambers of commerce and local health councils, are attracting enthusiastic interest throughout the country. Although this trend in health education is gaining momentum, little effort has been made to evaluate its effect on the public and the participating agencies. The Philadelphia experience illustrates the need for critical evaluation.

History of the Fairs

The first fair was held May 15-22, 1954, from 11 a. m. to 9 p. m. daily, in Reyburn Plaza, an open court opposite City Hall in the heart of Philadelphia. Health tests and exhibits presented by 40 agencies were housed in gay canvas booths. A large tent served as a film theater.

Despite one day of unfavorable weather, 52,000 persons attended the fair, and more than

7,000 received chest X-rays, blood and hearing tests, diet evaluations, height and weight measurements, and tests of strength and skill. Public reaction was favorable.

Sponsors of the fair decided that it should, if possible, be a yearly event. Most of the agencies felt that the major objectives had been accomplished fairly well though some adverse opinions were expressed regarding street noise and the difficulty in handling the flow of visitors. The consensus was that the location had been satisfactory.

Tentative plans were made late in 1954 for a second fair. The executive committee was broadened to include more members from voluntary and official health agencies. Two new committees were added, one to expand the health testing program and one to promote attendance through community groups. Again, financing was through contributions from participating agencies. The budget was \$12,250. This fair was scheduled for the same location at the same hours as in 1954, but the fair week was shortened to 6 days, May 16-21, 1955.

Aided by a week of favorable weather, attendance in 1955 climbed to an estimated 80,000 (28,000 over the first year), and the number of health tests given exceeded 20,000. Increased newspaper and radio coverage, expanded testing, improved exhibits, and more extensive programming helped increase attendance also. Forty-one agencies presented exhibits, demonstrations, health tests, films, and programs.

Organization and Operation

The health fair required days and hours of spade work by the groups and agencies that conceived the idea and by the committees and numerous subcommittees. In addition to determining policy regarding arrangements for exhibits, publicity, and financing, the steering committee developed the objectives, opened communication lines, and advised on problems in professional relationships. Presentation of the fair was the responsibility of the executive committee. To coordinate planning for the forty-odd agencies and to handle the details of booth construction and rental, the executive committee hired a fair manager 3 months before the fair. The manager's booth was located

illustrated with large, clear photographs often attracted study. Demonstrations and other eye-catchers increased attendance at exhibits.

Are the exhibits and health tests staffed by attendants qualified to provide desired information or make needed referrals?

Attendants at exhibits should be well informed about the functions of their own agency, the purposes of the exhibit they represent, and the objectives of the health fair. They should be able also to refer inquiries to other sources of information. Orientation can be accomplished by the agency itself and by a general briefing for all attendants.

Incomplete information on the part of persons administering the health tests may have contributed to the failure of some fair visitors to identify health tests when they were questioned on leaving the fair. One test in particular was interpreted inadequately and resulted in undue concern over failure to attain an average score.

Those giving health tests should receive short, intensive training to familiarize themselves with the purposes of the test, its limitations, and the exact interpretation of the results. Explanatory pamphlets and posters will support the explanations by the attendant.

Misconceptions result from failure to explain the health tests. For example, some individuals confuse a test for diabetes with a test for venereal disease. Listing all tests on the program and posting the list in a conspicuous place will tend to relieve such confusion.

Are presentations readily accessible?

Exhibits, health tests, and other presentations should be accessible to everyone. Lanes between rows of booths should provide for an unobstructed flow of traffic. If it is necessary to keep lines of people waiting to take tests and view exhibits, the lines should be arranged to avoid blocking other displays. Announcements over a public address system aid in directing visitors to uncrowded exhibits and tests.

Have the programs had careful planning?

In general, the main objective of health fair programs is to motivate good health practices.

One method of developing a program is to plan with agencies contributing to the chosen theme. Each minute in a program should be planned to contribute to the objectives.

The Learning Process

Health education studies have shown that what people learn reflects their immediate personal interests and concern. Simply stated, a hungry man notices a restaurant that a satiated person might overlook. In general, without motivation, learning does not proceed. Other studies have shown that the pattern or organization of motives in people is quite individual and perhaps unique.

What implications do these facts have for a health fair?

In any group of people assembled at a fair, some will not be motivated by the subject or theme. Others may be strongly motivated in areas served by some of the material but not as much in others. Since patterns of motives, as well as learning capacities, are individual, each person would be expected to learn at his own pace and in his own direction.

On the basis of these principles, it could be predicted that the amount of information gleaned from the wealth of material at a health fair would vary from person to person. Also, no individual would learn exactly what is learned by any other. A health fair cannot be equally successful for all participants, nor is it at all successful for some.

One might maintain that moderate success might still be achieved with individuals who have a personal concern with health. This would be true if enough people had such concern and if the material presented were appropriate. Preliminary explorations, however, suggest that relatively few people have concerns that they identify with the need to improve health practices. Of course, the health worker knows that a person's health status strongly influences his ability to function and obtain what he wants, but most people either do not know this or behave as if they do not know, with gross indifference to their health.

These problems pose a difficult question for health educators. How can we help people improve health practices when they do not believe they have health needs?

such that the limited educational activity of the health fair could not reasonably be expected to achieve them by itself.

4. Within the limitations of the design of the inquiry, it could not be shown conclusively that the fair succeeded in increasing knowledge about local health services.

The intermediate objectives, as stated, were not met in full. In view of this, the participating agencies recognized the need for more realistic objectives. Agency discussion of the evaluation resulted in a review of individual and group philosophies of health education, a greater appreciation of the need for evaluating other efforts at health education, and immediate plans to exploit more effectively the education potential of the fairs. Self-evaluation by the participating agencies indicated that most felt they had progressed toward goals. Some reported that use of their services increased following the fair.

Implications for the Future

The findings of the evaluation have many implications. In this context, it is less important to ask whether 48 percent participation in health tests met expectations than it is to ask how to increase participation. Similar questions may be asked about the other findings.

Are program objectives realistic and can they be achieved?

Specific objectives should be agreed upon by all participants early in the planning stage. Evaluation of a program seldom can be effective if objectives are vague. For evaluation to be effective, long-range objectives essential to initial planning must be associated with realizable short-term objectives. This process can be facilitated by including persons responsible for the evaluation early in the discussions.

What audience are we trying to reach?

Identification of the desired audience should be made early because the entire process is colored by that decision. The nature of the Philadelphia health fair, with its wide range of messages, made it difficult to identify a specific audience, although adults were more desired than youngsters. It was felt that chil-

dren, welcome of course, receive health education more effectively through schools.

The location of the fair, in the heart of the city, and the means used to promote it explain in part the presence of relatively large numbers of young people, men, and visitors of relatively extended schooling. The fair, with its gaiety and hubbub, naturally attracted many visitors who were in the neighborhood. When asked how they happened to come to the fair, the men, the young people, and those with extended schooling responded much more frequently than others that they were motivated by seeing the fair itself. This supports the idea that the sight and sound of the fair will bring more visitors than advertisement in the newspapers. The less extensively schooled, the older adults, and, to a lesser degree, women, tended to stress newspapers and public advertising as their reason for attending the fair. This occurred despite the fact that these groups probably had less exposure to these forms of public communication than the others. Had the fair been held in another part of the city, quite different groups might have attended.

Findings on the nature of the audience should not be attributed to the single factor of location. In tuberculosis case-finding programs, participation is poorest in precisely the same population groups whose attendance was poorest at the health fair. Hochbaum (2) suggests that differences in motivation also may help to account for the nature of the audiences.

Do the exhibits permit rapid inspection and learning?

The 1955 health fair included exhibits, health tests, films, and health programs. Although to view all the exhibits, films, and programs and participate in all tests would undoubtedly have required several hours, the median amount of time spent at the fair was only 45 minutes, or only 1 minute for each of the presentations offered. There is no reason to believe, however, that an individual could not have had a satisfactory learning experience if he had spent the 45 minutes in taking 2 or 3 health tests, viewing a film, and seeing several exhibits.

Exhibits that were top heavy with copy received little attention, but displays consisting of only a few lines of carefully edited copy and

activities. Additional critical evaluation may give information about the value of health fairs to a community, their priority in health education, and their opportunities for providing individual consultation. Although their value in building relationships and improving cooperation among community agencies seems evident, their educational values for the public are not certain.

Through further research, it may be possible

to determine the educational potential of the health fair and discover effective ways of realizing such potential.

technical publications

Research and Training Grants and Awards of the Public Health Service

Information Statement

PHS Publication No. 415. Revised, October 1956. 29 pages.

Included in this revised brochure are several new programs initiated subsequent to July 1956, such as health research facilities, senior research fellowships, and mental health career teacher grants. It has, in addition, information on research grants, field investigation grants, career investigation grants, research fellowships, traineeships, and training grants.

The booklet describes liberalized policy governing the budgeting of funds and the use of unexpended funds in approved grants, and reflects the increase in stipends under the traineeship and research fellowship programs.

The Public Health Service in Occupational Health

PHS Publication No. 490. 1956. 16 pages; illustrated. 20 cents.

This booklet describes the work of the Public Health Service in its 40 years of research in occupational

health hazards. Photographs depict various phases of program operation, and the narrative material is intended for a general rather than a specialized audience.

The publication points out that, while great strides have been made in eliminating occupational disease in the past century, new hazards are posed by materials and processes being constantly introduced by a dynamic technology.

Occupational Health Program activities now encompass research and field studies, promotion of preventive health services in industry, and training and consultation services, all directed toward achievement of greater health protection for the production force of the Nation.

Citizen Participation in Public Welfare Programs Supplementary Services by Volunteers

Social Security Administration. By Evelyn G. Weller and Elizabeth B. Kilborne. 1956. 46 pages. 20 cents.

Addressed to the staffs of State and local welfare agencies, this booklet aims to encourage agency personnel to provide more opportunities for citizen participation in community service.

The publication discusses supplementary services and offers suggestions for developing volunteer services and for the orientation, training, and supervision of citizen volunteers.

Other social agencies interested in initiating or extending volunteer services will also find the discussion helpful.

National Library of Medicine

PHS Publication No. 507. 11 pages.

Services of the National Library of Medicine, formerly the Armed Forces Medical Library, are listed in this folder. Included are library hours; loan procedures; and photo-duplication, reference, translation, history of medicine, art section, and publication services.

This section carries announcements of all new Public Health Service publications and of selected new publications on health topics prepared by other Federal Government agencies.

Publications for which prices are quoted are for sale by the Superintendent of Documents, U. S. Government Printing Office, Washington 25, D. C. Orders should be accompanied by cash, check, or money order and should fully identify the publication. Public Health Service publications which do not carry price quotations, as well as single sample copies of those for which prices are shown, can be obtained without charge from the Public Inquiries Branch, Public Health Service, Washington 25, D. C.

The Public Health Service does not supply publications issued by other agencies.

In general, it appears necessary to plan health programs in such a way that the unique needs or motives of each individual can be served insofar as possible. Efforts should be made to tie in with whatever personal needs the individual believes he has. Program development must be based on valid information about the concerns of persons whose cooperation is sought. Health consultation by a well-informed staff at the fair booths offers the possibility of uncovering some of these needs, and, at least partially, of meeting them.

Theory Into Practice

Theories developed from the 1955 evaluation became practice in 1956, when the third annual health fair was held October 12-13 and 15-18 in Reyburn Plaza. The evaluation had provided definite guidelines for presenting exhibits and tests. As a result visitors were given a better opportunity to learn about personal and community health, and the services of health and welfare agencies.

More realistic short-term objectives were developed along with suggestions to participants for achieving them.

Store window posters and mass distribution of fliers were not used to promote the fair because the evaluation had shown them to be of limited value in attracting an audience.

A subcommittee on volunteer training was organized to assure that attendants at the booths were better informed about the health tests, the exhibits, the fair in general, and their own agency in particular.

On the recommendation of the volunteer training committee, each agency provided descriptive material on its services for the use of persons staffing the booths and a list of community resources to assist them in making referrals.

The cancer society, the department of public health, and many of the other agencies met with the staff members and volunteers who were to man their health tests and exhibits.

These meetings provided facts about the fair sponsors: background, history, functions, and purposes; why the particular agency was taking part; its relationship to other agencies; and the value of health consultation.

Organizations presenting health tests explained to their staff members the purposes and limitations of the tests, how those examined would learn of the results, and where tests are available regularly.

Because the evaluation had pointed up the need, special efforts were made to improve interpretation to those examined of results of the tests.

Mimeographed sheets, listing the purpose of the particular test, what constitutes a normal result, and the mechanics of followup, were distributed at the fair.

A sign posted near the clinitron, the device for testing sugar content of blood, explained that a blue color in the test sample meant a normal condition and that a colorless sample indicated possible diabetes. In this way, people viewing the operation of the clinitron could watch the progress and final result of a test. The use of leaflets and signs in front of booths reduced anxiety about test results and gratified curiosity.

Spot checks at the 1956 fair revealed that persons staffing the booths were better informed about exhibits, tests, and agency and health fair purposes than in the preceding year.

Summary and Conclusions

To summarize the Philadelphia experience with three health fairs, we would say that in planning a health fair or any other health education activity it is necessary to set realizable short-term objectives as well as long-range objectives. The attainment of these will provide encouragement to participating groups. Persons responsible for evaluation should be included as early as possible in program planning. By making evaluation results available to all concerned—in Philadelphia these were the sponsoring and participating agencies—programs in the future can be improved.

The location of the fair greatly determines who will attend. Fairs should use proved techniques for attracting an audience and motivating it to positive steps. Careful instruction is essential for those who are to give the health tests and explain exhibits to visitors.

A health fair may be viewed as a project which is linked with other community health

Table 1. Number and percentage of patients with malignant neoplasms, according to site, by race, Tennessee tumor clinics, 1947-49

| Site | Total | | White | | Negro | |

Percentage distributions by site for a broader group of patients are available for two other southern areas for recent years, Atlanta, Ga., 1947 (1), and Birmingham, Ala., 1948 (2). The Atlanta and Birmingham studies include cancer patients seen, diagnosed, treated, or under observation by hospitals, clinics, and physicians while the Tennessee cases are made up entirely of clinic patients. Although not strictly comparable, the data for the three studies are offered in table 2 and figure 3.

As would be expected, the percentage distributions by site seem about the same for the

Figure 1. Percentage of cancer cases admitted to tumor clinics, by site, Tennessee, 1947-49.

Figure 2. Percentage of cancer cases admitted to tumor clinics, by site and race, Tennessee, 1947-49.

Atlanta and Birmingham areas, but they differ from those for Tennessee. A larger proportion of the patients admitted to the Tennessee clinics had cancer of the buccal cavity, breast, and female genital organs. The percentage with cancer of the digestive organs was about one-half that of the Atlanta and Birmingham areas. The percentages were approximately the same for the respiratory system, male genital organs, and skin. One-fourth of the cancers in each of these three areas were of the skin.

In general, it seems that the clinic patients in Tennessee sought medical aid more often for

Life Experience of Cancer Patients in Tennessee Tumor Clinics

By SARA LOU HATCHER, M.A.

A STUDY of patients admitted to cancer clinics in Tennessee was begun by the Tennessee Department of Public Health in 1947. The purpose was to study the life experience of these patients according to type, site, and extent of the malignant neoplasms and other variables such as sex and age.

For the collection of data, the clinics complete a summary record for every patient admitted for the first time with a malignant neoplasm and send the record to the Tennessee Department of Public Health. The upper half of the record has identifying data, classification of the findings by type, site, and extent, and a summary of the treatment. The lower half provides space for recording the status of the patient at yearly intervals after diagnosis. For information regarding status of patients (living or dead), the clinic is queried at yearly intervals after diagnosis. If the clinic is unable to give the status of the patient, a query is sent to the health department in the county where the patient is a resident. Also, data regarding cause of death are obtained from death certificates and are entered at the bottom of the record.

Followup data are available for 5 years for patients admitted to the participating clinics in 1947, 1948, and 1949. The factors considered in this discussion are the site and extent

of the malignant neoplasms and the race of the patient. It is realized that other factors, such as age and sex, may influence the probability of death from cancer, and plans are in progress to include these in a more extensive report.

There were 2,476 patients with malignant neoplasms admitted to the clinics during the 3 years 1947, 1948, and 1949. Of these, 1,645 (approximately two-thirds) were white, and 831 (one-third) were Negro patients. The distribution of the patients according to the site of the cancer is shown in table 1 and figure 1. Cancer of the skin and female genital organs accounted for more admissions than any other site, with approximately one-fourth of all admissions for each. Other sites in order of frequency were breast, buccal cavity and digestive organs, male genital organs, and respiratory system. Cancer of all sites for which less than 75 persons were admitted were included in the "other" group. This group includes cancers of the urinary system, brain, bone, lymphatic system, and so forth.

The percentages by site vary according to race (table 1, fig. 2). The two most common cancer sites for the white patients were the skin and female genital organs. For the Negroes they were the female genital organs and breast. Nearly two-fifths (38.2 percent) of the white admissions were for cancer of the skin while only 2.9 percent of the Negro patients admitted had skin cancer. About 41 percent of the Negroes had cancer of the female genital organs compared with 17.4 percent of the white patients.

Miss Hatcher, a senior statistician in the Tennessee Department of Public Health, presented this paper at the meeting of the Southern Branch of the American Public Health Association in Tulsa, Okla., in April 1956.

nearly 50 percent had regional involvement; and in approximately 30 percent remote metastasis was present.

Probability of Death

The preceding discussion has dealt with the characteristics of the cases admitted. The remainder of this paper will be concerned with the probability of survival or death of these

patients according to site and extent of the malignant neoplasms at the time of admission and the race of the patient.

The rates for probability of death have been obtained by the adaptation of life table methods used for tuberculosis patients (3) and recommended by Berkson (4) for survival and death rates of cancer patients. By this method each person whose status is known is considered as being at risk of death for the year of observa-

cancer of the so-called accessible sites while the broader groups of patients in Atlanta and Birmingham were seen for the inaccessible sites as well.

Extent of Lesions

It is of interest to know the percentage distribution of the patients admitted to the Tennessee clinics according to the extent of their lesions (table 3 and fig. 4). Of the 2,476 patients, 600 (24.2 percent) were stated to have localized lesions; 719 (29.0 percent) were stated to have regional involvement; and 435 (17.6 percent) were thought to have remote metastasis at the time of admission. The extent was not classified for 722 (29.2 percent) of the lesions. The following discussion of extent relates to the 1,754 patients for whom extent was stated.

As would be expected, cancer of the inaccessible sites was generally discovered late. Remote metastasis was more often present on admission for cancer of the digestive and respiratory systems than for any other site. The percentage of breast cancer with remote metastasis was relatively small, but more than 60 percent in both races had regional involvement. The distribution of cancer of the breast according to extent was the same for both white and Negro patients. This was also true for cancer of the female genital organs. For malignant neoplasms of the buccal cavity, di-

Figure 3. Percentage of cancer cases, by site, Tennessee tumor clinics, 1947-49, Atlanta, Ga., 1947, and Birmingham, Ala., 1948.

gestive organs, respiratory system, and male genital organs, the percentage with remote metastasis was somewhat greater for Negro than for white patients.

In only a small proportion was there remote metastasis of the skin lesions on admission. However, the proportion of Negroes with regional involvement was much larger than for white patients. More than three-fourths (78.8 percent) of the malignant neoplasms of the skin in white patients were localized compared with 40 percent in Negroes.

Since such a large percentage of the white patients had skin cancer and most of these lesions were localized, the data excluding skin sites are given in table 3 and figure 5. When skin cancer is excluded, the percentages of the lesions in each extent group are practically the same for the white and Negro patients. These percentages are as follows: Approximately 20 percent for each race were localized;

Table 2. Percentage of patients with malignant neoplasms, by site, participating clinics in Tennessee, 1947-49, Atlanta, Ga., area, 1947, and Birmingham, Ala., area, 1948

| Site | Tennessee | Atlanta ¹ | Birmingham ² |
|-----------------------|-----------|----------------------|-------------------------|
| Total | 99.9 | 100.0 | 99.9 |
| Buccal cavity | 8.0 | 3.7 | 4.1 |
| Digestive organs | 8.0 | 17.8 | 17.7 |
| Respiratory system | 3.3 | 4.7 | 5.2 |

² SOURCE: Reference 2.

Figure 7. Mortality of cancer patients admitted to tumor clinics, by site, during 5 years of observation, Tennessee, 1947-49.

tality for sites other than digestive and respiratory systems was more gradual (table 4, fig. 7). When the cumulative percentages by years are shown graphically the lines for buccal cavity, breast, female genital organs, and male genital organs almost coincide. Approximately one-third of those with cancer of either of these four sites died during the first year of observation with the remainder of the deaths occurring during the next 4 years. The mortality of those with malignant skin neoplasms was much lower, with 10.8 percent dead within the first year and increasing until 30.6 percent had died by the end of the 5 years of observation. Figure 7 points out that mortality was highest for the inaccessible sites, next highest for the partially ac-

cessible sites, and lowest for the accessible site of skin.

How does extent of the lesion affect these rates? This can be seen for white and Negro patients in table 5 and figure 8. If remote metastasis was present at the time of clinic admission, the mortality was the same for the two groups; approximately three-fourths of all were dead at the end of the first year and by the end of 5 years more than 90 percent were dead. When there was regional involvement, approximately 30 percent of the white patients and 40 percent of the Negroes were dead by the end of the first year. Two-thirds (66.3 percent) of the white patients and three-fourths (76.2 percent) of the white patients and three-fourths (76.2

Figure 8. Mortality of cancer patients (excluding skin) admitted to tumor clinics by extent of lesion and race, during 5 years of observation, Tennessee, 1947-49.

Table 5. Percentage of patients with malignant neoplasms of sites excluding skin dying during first 5 years of observation, by known extent and race, Tennessee tumor clinics

| Period of observation | Localized | | Regional involvement | | Remote metastasis | |
|-----------------------|-----------|-------|----------------------|-------|-------------------|-------|
| | White | Negro | White | Negro | White | Negro |
| First year | 16.0 | 20.0 | 31.1 | 40.8 | 75.7 | 74.2 |
| First 2 years | 26.6 | 27.9 | 47.9 | 58.5 | 86.2 | 87.7 |
| First 3 years | 33.4 | 36.0 | 57.6 | 68.9 | 90.8 | 90.0 |
| First 4 years | 41.2 | 43.6 | 62.6 | 73.1 | 94.1 | 91.8 |
| First 5 years | 45.1 | 51.1 | 66.3 | 76.2 | 94.6 | 92.4 |

Figure 4. Percentage of cancer cases admitted to tumor clinics, according to site, by race and extent, Tennessee, 1947-49.

tion. Each of the persons with unknown status is counted as being exposed to one-half year of experience since it is probable that some have died and others have survived. The status of 92.2 percent of 2,476 patients admitted to the clinics was known at the end of 5 years. Thus, 7.8 percent of the patients were lost because of unknown status.

Nearly two-thirds (62.4 percent) of all patients admitted were dead by the end of 5 years of observation. The percentages vary according to the site of the malignant neoplasm (table (4 and fig. 6).

The highest mortality followed cancer of the digestive organs, with 85.9 percent of the patients dead within the first 5 years. For the respiratory system, 80.9 percent of the patients died during the 5 years. Next in order were cancer of the male genital organs (69.5 percent dead), breast and female genital organs, with 66.5 percent of patients with cancer of each site dying, and cancer of the buccal cavity, for which the mortality was 65.4 percent. The probability of dying with cancer of the skin during the 5 years was only 36.6 percent.

How is the mortality for these sites distributed over the 5 years? Approximately two-thirds of those with cancer of the digestive organs or respiratory system died during the first year of observation. It may be remembered that a relatively large percentage of the patients with cancer of these two sites had remote metastasis on admission. As will be shown later, most of the patients with such extensive involvement died during the first year. For patients with cancer of the digestive organs and respiratory system, the percentage dying the first year was as high as the percentage at the end of 5 years for patients with cancer of the buccal cavity, breast, female genital organs, and male genital organs. The increase in mor-

To feed homeless and displaced people following a disaster or a possible nuclear attack upon this country requires advance planning. Radioactivity from fallout might further complicate emergency feeding following a disaster.

Emergency Feeding

By ROY E. BUTLER, M.D.

THE LATEST assumptions of the Federal Civil Defense Administration envisage the possibility of attack with thermonuclear weapons on many major cities in this country. The destruction of cities which are critical target areas would preclude adaptation of civil defense methods used in Europe in limited and localized bombings of the Second World War.

At that time Britons found that a bombed out worker was helped to get on with the job if he had a cup of tea and cakes. On being notified of a bombing incident, the Queen's Messengers, staffed by members of the Women's Voluntary Service, proceeded to the site with food-equipped vans and carried out emergency feeding operations. The warm meals served to bolster morale. Cash with which to buy food or restaurant meals, an attempt to restore normal food channels, and the provision of a small amount of food without particular regard to nutrient content were the usual methods of feeding the homeless. Mass feeding usually was limited to a day or two.

The dislocation of populations surviving or anticipating urban disaster would necessitate mass feeding on a huge scale for protracted pe-

riods. Regions near critical target areas in this country might be deluged by displaced thousands to be fed and housed under relatively primitive conditions. The salvage of food from areas contaminated by radioactive dust or water would pose hazards that might be multiplied several times by the concomitant use of chemical and biological warfare agents. Sanitary water supply, sewage and waste disposal, and food preparation would be difficult to provide in such an event.

The handling of some of these problems is described in "Emergency Mass Feeding—Instructor Course," a publication developed by the Department of Defense and the Federal Civil Defense Administration (1).

Those feeding evacuees immediately after attack would have to improvise ways of preparing available food. The need to appease hunger would take priority over attempts to prevent disease, to vary diet for different age groups or conditions, or to balance the nutrient content of emergency menus. It may be impossible to satisfy traditional food patterns.

Federal and State Cooperation

Ever since its establishment in January 1951, the Federal Civil Defense Administration has been helping States prepare for a war emergency. In the event of a general attack, FCDA would direct all Federal activities concerned with the saving of life and the relief of suffer-

Dr. Butler is assistant chief of Health Emergency Planning in the Office of the Surgeon General, Public Health Service. This paper is based on a talk delivered October 12, 1956, at the annual meeting of the West Virginia State Nutrition Council, Keyser, W. Va.

percent) of the Negro patients were dead within 5 years after admission. As would be expected, mortality for those with localized lesions was lower for both the white and Negro patients.

What were the causes of death for those patients who died? The deaths were studied according to the cause of death as given on the death certificate. There were 1,497 deaths among the 2,476 patients admitted. The cause of death was definitely stated as cancer for nearly three-fourths (72.5 percent) of the deaths for both the white and Negro patients. It would be of interest to study these cancer deaths to see how many were caused by the same type of cancer that was diagnosed on admission and how many were due to another type. Perhaps this can be done in subsequent studies.

Summary

Followup data are available for 5 years for patients admitted to the participating cancer clinics in Tennessee in 1947, 1948, and 1949.

Of the 2,476 admissions to the clinics during these 3 years, approximately one-fourth were for cancer of the female genital organs and one-fourth for skin cancer. Of the white patients, 38.2 percent had skin cancer while only 2.9 percent of the Negro patients had skin cancer.

Thirty-three percent of the patients died during the first year; 46 percent were dead by the end of the second year; 54 percent, by the end of the third year; 59 percent, by the end of the fourth year; and 62 percent were dead by the end of the first 5 years of observation. The sites with the highest mortality were the diges-

tive organs and the respiratory system. The percentage dying with cancer of these sites during the first year was as high as the percentage at the end of 5 years for patients with cancer of the buccal cavity, breast, female genital organs, and male genital organs.

More than 90 percent of both white and Negro patients with remote metastasis at time of admission to the clinic died within the first 5 years. Two-thirds of the white patients and three-fourths of the Negro patients with regional involvement on admission were dead within 5 years. Mortality among those with localized lesions was lower for both white and Negro patients.

• • •

Detailed data on the survival status of the clinic patients and the method used in calculating the probability of their survival or death can be obtained in mimeograph form from the author.

Cardiovascular Disease Abstracts

A new publication devoted to abstracts in the cardiovascular disease field is being issued in 1957 by the Excerpta Medica Foundation with the support of the National Heart Institute, Public Health Service. The first volume, containing approximately 800 pages, will cover the world's medical literature.

Among subjects covered in separate chapters, in addition to the basic medical sciences, will be diseases of the pericardium, myocardium, and epicardium; rheumatic fever; congenital cardiovascular disease and pulmonary circulation; hypertension, peripheral vascular disease, hypothermia, artificial circulation, and special problems of the heart patient; and rehabilitation.

normally carried in the home, in the retail store, in wholesale houses, and in the processing plants. They are attempting to determine what percentage of the normal supply would probably be lost in a nuclear attack, in order to determine whether processed foodstuffs should be stockpiled to meet essential demands until food processing can again fill the demand. I feel confident that if their studies reveal serious shortages of particular foodstuffs, they will recommend that adequate stockpiles be formed.

"In this regard the Federal Civil Defense Administration has recommended that all households have a 7-day supply of food on hand."

Nutrition Planning

Although local distribution of food and emergency feeding operations are a welfare responsibility, it is expected that the health organization will supervise sanitation procedures relating to emergency food preparation and waste disposal. In addition, FCDA in the manual entitled "United States Civil Defense—Health Services and Special Weapons Defense" has recommended specific responsibilities for the health services in the field of nutrition (3).

The health and welfare services must cooperate in providing a nutritionally adequate supply of food for emergency feeding. To achieve this purpose, the welfare service should have a qualified nutritionist on its staff, the health department should include a nutrition service, and each program should be fully informed of the other's progress. The nutrition program of the health department should be directed by a qualified medical nutritionist who will advise on the suitability of the dietary planned for the local population.

With food shortages and conflict of needs and priorities, wise allocation of food supplies will be part of the price of survival.

How many calories must be supplied each individual cannot be specified. That will depend on the supplies of food and the activities and size of the population, but the supply should support life, the capacity to work, and morale. Periodic physical surveys of the population may be necessary to determine nutritional status and to justify and guide rationing policies.

Various recommendations have been made to guide families as to maintaining standby food supplies for emergency use. It has been assumed that households ordinarily would have 2 or 3 days' supply of food on hand.

The Federal Civil Defense Administration recommended a 7-day supply for the individual home after it became apparent in 1954 that thermonuclear weapons would produce considerable fallout. Dangerous radioactivity after an attack will keep people inside shelter for 7 to 10 days or more. When surviving homes are opened to shelter the homeless, the supply of food and water also will have to accommodate additional numbers.

In the preparation and distribution of food for large groups, observance of good sanitation practices will be difficult under emergency conditions. New or unfamiliar strains of bacteria may lead to outbreaks of diarrheal disease. Families may resist attempts at separation, and not merely because they like to eat together or because they are accustomed to their own ways of cooking and seasoning.

If mass feeding is necessary for only a few days, the problems cited will be relatively unimportant, but with extended periods of feeding homeless populations, for weeks or months, the problems may lead to trouble if not a complete breakdown of the operation. The prospect of feeding thousands or millions of homeless families emphasizes the value of adequate planning and efficient organization to proceed with any semblance of order.

Belsen Experience

Emergency feeding for the extremely malnourished or starving should receive some comment.

The use of protein hydrolysates to rehabilitate starving prisoners after the surrender of Germany in World War II has evoked considerable interest. Protein hydrolysates are mixtures of amino acids prepared by splitting a protein with acid, alkali, or enzyme. Several organizations in this country produced these substances for oral and intravenous use.

I well remember a news conference in London in May 1945, at which a British nutritionist

Salvation Army canteen provides ample helpings of cold ham and hot lima beans to the hungry and homeless during a flood disaster.

ing. Some States and local communities have their own programs for training civil defense workers. Each should have a plan for stockpiling food and medical supplies.

FCDA has placed responsibility for emergency feeding in its Welfare Office. This organizational pattern has been repeated in State civil defense organizations, where similar responsibility is centered in the welfare and public assistance programs. However, by FCDA-delegated authority, the Department of Agriculture has Federal responsibility for maintaining adequate emergency food supplies for target and support areas.

In discussing the problem of food supply in a national emergency, Federal Civil Defense Administrator Val Peterson made the follow-

ing statement to the House Agriculture Committee on March 7, 1956 (2):

"In the first phase of an emergency, the problem may be less one of the reserve stocks of food than one of distribution.

"After the first few days or weeks of an attack, however, when processed food stocks have been depleted, then raw materials must be processed and placed in the distribution system.

"The question of how quickly the processed foods will be used up will, of course, depend upon the number of persons surviving to consume the food, the total amount of food, and the availability of transportation to distribute the food where it is needed.

"The Department of Agriculture is studying the problem of the amount of processed food

fense have been appropriated to the department, nor are there any budgetary provisions whereby additional personnel can be employed for the purpose.

According to the plan, the State director of public assistance will function as the civil defense chief for the division of welfare and will designate the department's nine administrative districts as areas in the civil defense program. One of the larger cities or towns is the headquarters and center of operation. The districts cover 55 counties.

In each area, the present district administrator of the department is the area chief for his district, and in each county, the county director is the county chief.

The department's workers, in their respective counties, will coordinate welfare needs with the county courts, county enforcement authorities, and the Community Chest, Salvation Army, Red Cross, and other voluntary agencies. All will function under the command of the county director for civil defense.

In the last few paragraphs, I have paraphrased portions of the annual report of the West Virginia State Department of Public Assistance for the fiscal period July 1, 1954, to June 30, 1955 (4). Now to quote directly:

"Fortunately the department of public assistance in West Virginia operates a division known as the Division of Commodity Distribution. Its program requires warehouses, the use of sidings, and trucks throughout the State. The department plans to develop that division, from that nucleus, into a wide range of volunteer services with trucks, cars, or whatever else is required in bombing emergencies to operate from the various sidings or warehouses which have been set up for the purpose of delivering foods and any other government-donated materials to the points of disaster."

In addition, I might add, the West Virginia Division of Commodity Distribution will have the responsibility of procuring food and goods from neighboring States. Formal agreements for the purpose have been negotiated by the West Virginia Department of Civil Defense.

The report (4) of the division of commodity distribution for the fiscal year 1955 indicates the magnitude of its normal operations. Dur-

ing the year the division provided commodities to 250,000 public assistance clients, served 11,961 persons in 84 State and private institutions, 13,209 children in summer camps, and 163,064 children through the school lunch program. Under disaster relief 2,500 persons received food.

The figures in the following list illustrate 7 different food items from a group of 19 distributed by the division in varying amounts over the same year (4). This is a partial indication of the experience one State department of public assistance has had in warehousing and distributing foods and of its ability to carry on this mission in a national emergency.

NRC Suggestions

Immediately bearing on this whole problem and summarizing the essential elements of emergency feeding is a statement of the Food and Nutrition Board, National Research Council. The statement was published in 1951 (5):

"The Committee on Dietary Allowances has been requested to make suggestions which may assist State and local civil defense organizations in formulating plans for emergency feeding. The committee feels that certain general principles should govern all such plans. Of paramount importance is the inclusion of personnel with broad training and experience in nutrition in civil defense organizations at the highest administrative level. The efficacy of any feeding program during a period of disaster will be dependent on integration and collaboration with other essential services.

"In the event of enemy attack on this country, immediate and severe disruption of food supplies in the affected area may ensue. The initial problem will be one of supplying water and of distributing whatever foods may be available. It is unrealistic to expect to provide an

A classroom in a school, serving as an emergency relief center, is used for storing food and other supplies distributed to flood victims.

described his experience at Belsen after liberation of the concentration camp.

The prisoners fought madly against attempts to administer intravenous injections of protein hydrolysate material because they were convinced that the needles contained gasoline, infections agents, or other toxic substances. They strongly resisted all efforts to make them take the protein compound by mouth. Forced feeding in quantities to meet metabolic requirements was similarly unsuccessful. Much more success was achieved with milk, eggs, sugar, and other familiar articles of food.

We cannot expect starving people to be rational.

Under the circumstances related, prisoners of professional status, physicians and nurses included, could not be entrusted with the care and feeding of other prisoners. Apparently their harrowing experiences and physical and mental condition affected their ethical and professional standards.

We hope that never again will such a degree of malnutrition be encountered.

Voluntary Agency Feeding Programs

The value of adequate planning and organization has long been recognized by the American National Red Cross, which has had ex-

tensive experience with meeting the emergency needs of disaster victims. Each local chapter has a food committee whose members are selected from dietitians, nutritionists, home economists, wholesale grocers, and managers of school lunchrooms, restaurants, and hotels.

An agreement, dated February 6, 1953, between the Red Cross and the Federal Civil Defense Administration provides for cooperative assistance in disasters other than those induced by enemy attack. Undoubtedly, to relieve a national disaster, the Red Cross would contribute to the full extent of its capacity. Likewise, the experience of the Salvation Army and the school lunch groups with mass feeding will surely be applied.

West Virginia Program

A good example of planning and organization by a State is found in West Virginia.

The civil defense program of West Virginia features the assignment of separate disaster functions to each of the State departments. The welfare functions of civil defense are centered in the West Virginia State Department of Public Assistance. Emergency welfare services are defined in the State plan as feeding kitchens, reception centers, and registration of disaster victims. No funds for civil de-

Community Surveys Yield New Services For the Chronically Ill

By ELEANOR L. RICHIE, M.A.,
and J. E. CANNON, M.D., M.P.H.

COMMUNITY INTEREST in the problems and service needs of the chronically ill and the aged has been increased in four Colorado counties in recent years by locally developed programs of household surveys and studies of nursing homes and other health facilities. The county programs received general guidance and financial assistance from the Colorado State Department of Public Health under a gerontology grant from the W. K. Kellogg Foundation from June 1953 through December 1956.

The participating counties were El Paso, Mesa, Otero, and Weld. In each, there is an organized local health department, either a college or a junior college, and numerous civic, professional, business, and community service organizations. Through such agencies and groups, new steering and executive committees were formed to plan the studies of the chronically ill and the aged. Subcommittees and voluntary workers assisted in carrying out the surveys. Community organization for the programs centered in the principal cities, but the household surveys and nursing home studies were countywide. Population coverage in the household surveys averaged 50 percent or better.

El Paso County has a population of about 115,000, including some 30,000 military personnel stationed in or near Colorado Springs, the county seat. The city, situated at the foot of Pike's Peak, is the financial, trading, cultural, and residential center of a mining, agricultural, small industry, and tourist trade area. Mesa County, on the western slope of the Rocky

Mountains, is a fruit-growing, livestock-raising, and mining area of about 50,000 population, including Grand Junction, the county seat, with about 30,000 population. Otero and Weld Counties, on the plains east of the mountains, are occupied with agriculture and related industries. They have populations of about 30,000 and 75,000, respectively. The principal cities are La Junta and Greeley, which have about 10,000 and 25,000 inhabitants.

Desire for Action

In the four counties, a full-scale viewing of the interrelated problems of the chronically ill and the aged was afforded the committees for the studies, the many volunteer canvassers in the household surveys, and the smaller groups who surveyed nursing homes and other facilities. Heartfelt interest created by this personalized experience brought demand for action and immediately led to new community services. It stimulated plans for more comprehensive supplementation or reorganization of existing services in the future.

Lasting results of the study program cannot be fully assessed at this early date. Nevertheless, new activities and plans reported to date indicate that numerous postsurvey recommendations made by the study committees are now being implemented.

New Starts and Future Goals

In El Paso County, the foremost recommendation based on the community studies was that programs and services for the chronically ill and the aged be better integrated. As a start toward the needed coordination, a health referral center has been set up with community support, resources, and personnel and with technical and financial assistance from the State department of public health. In addition, a special committee of the county medical society is studying ways to integrate the numerous clinic services in Colorado Springs and to provide more adequate medical care to the indigent and medically indigent of the county, through medical society panels or similar methods instead of the county physician system used in the past. Need for a central rehabilitation serv-

adequate diet or to designate specific nutrient requirements for this emergency period for any large population. Food to supply energy needs, preferably from bread, soups, or stews, should suffice for the first few days. As soon as possible, milk, including skim milk powder or evaporated milk should be provided, particularly to pregnant or lactating women, and to children from infancy through adolescence. Foods such as those mentioned above, in contrast to highly refined products, will furnish protein and other essential nutrients as well as energy. It should also be emphasized that a hot beverage, regardless of its nutrient content, is highly desirable early in an emergency feeding period.

"For infants, special plans should be made to assure maintenance of adequate supplies of canned evaporated milk, dry milk powder, cereals, and water for emergency feeding.

"It should be appreciated that drastic reduction of food intake for a few days, or even weeks, is tolerated reasonably well except by infants, by lactating women, by the sick and injured, and by those engaged in heavy physical work. This is particularly true if the calories that are available come largely from foods that furnish a variety of nutrients such as bread, potatoes, and milk, in contrast to foods such as sugar, sirups, and oils, which supply calories primarily. In longer periods of food shortage, special provision should be made not only for the more vulnerable groups indicated above but also for women who are pregnant.

"If emergency feeding must be continued for more than a few weeks, the problem of individual nutrients, as well as calories, assumes importance. Cognizance must be taken of needs for protein, thiamine, other B-complex vitamins, and ascorbic acid. Deficiencies of minerals and fat soluble vitamins are not likely to occur unless food shortages have persisted over several months.

"In any prolonged emergency, nutritional appraisal of the population by trained survey teams should be an integral part of the program. In this way, any deleterious effect of

the food allowance on health can be determined and plans for correction instituted.

"Care should be taken not to waste food due to possible contamination by atomic radiation. Food present in closed containers is safe in nearly all cases, if the outside of the container is washed. Food in open or broken containers exposed to radioactive materials should be monitored before use."

Conclusion

Adequate preparation for an emergency requires the development of an effective organization of competent people who are familiar with the problems to be expected and the best possible solutions for them. The emergency feeding personnel should be familiar with the responsibilities of the other civil defense services such as transportation, communications, supply, fire, and police. Adequate stocks of the proper foods would be helpful but cannot be anticipated. Improvisation and substitution would be the order of the day, and all efforts should be pointed toward existence and survival and the successful defense of the country.

Minor Venereal Diseases In the United States

By HENRY PACKER, M.D., Dr.P.H.

CHANCROID, lymphogranuloma venereum, and granuloma inguinale, the so-called minor venereal diseases, have declined markedly in the United States during the past 10 years.

This downward trend for the period 1946-55, depicted in the chart, is based on the number of cases of each of the minor venereal diseases reported to health departments in the continental United States. Reported cases of primary and secondary syphilis are included as a basis for comparing the rate of decline of the other venereal diseases.

Although the decline rates of the minor venereal diseases are of lesser magnitude than the 94 percent for primary and secondary syphilis, they are quite impressive.

The 10-year period subsequent to 1945 provides a reasonably uniform population upon which to base a trend. The number of civilian cases reported prior to this period was affected by the large proportion of young adults in the military services.

In probing the factors that may have contributed to the decline, consideration will be given to diagnostic procedures, contact investigation, and specific therapy of cases and contacts. Opinions regarding control procedures which may have influenced the trend were obtained from questionnaires submitted to venereal disease control officers in the 10 States from which the greatest numbers of cases were reported during the 1946-55 period.

Chancroid

Chancroid, the most prevalent of the minor venereal diseases during the decade under consideration, declined 68 percent. However, the use of definitive bacteriological methods for the

diagnosis of chancroid has been the exception rather than the rule in most clinics in this country, and this diagnosis usually represents a clinical impression reached after excluding syphilis. The designation of chancroid may therefore be considered as a convenient wastebasket category for nonsyphilitic ulcerative lesions of the genitalia.

At least one study of ulcerative genital lesions occurring in epidemic form among American soldiers in Japan has indicated that organisms other than *Haemophilus ducreyi* are capable of producing lesions of the genitalia resembling chancroid (1). Japanese workers (2) have reported that organisms bearing a morphologic resemblance to *H. ducreyi* were commonly found in prostitutes and that these could be easily mistaken for *H. ducreyi* with which they have no immunological relationship.

As mentioned above bacteriological methods are infrequently employed in the diagnosis of chancroid although their superiority to clinical criteria has been demonstrated repeatedly. Studies during the past decade in this country confirm earlier reports that smears may be expected to detect approximately 50 percent of infections, while cultures, the diagnostic procedure of choice, will identify 75 percent or more (3, 4). Although the skin test is positive in approximately 70 percent of cases, the limited sensitivity of this test during the early stages of infection and the persistence of a positive reaction after recovery make the skin test of limited value in early diagnosis. For this reason, it is presently used only to a limited extent in venereal disease clinics in this country.

There are no reports in the recent literature indicating that contact investigation has either been widely applied or has achieved any degree of success in controlling this disease. Our own experience in identifying sources of chancroid infection has been disappointing. Female sexual contacts of our male patients generally reveal neither genital lesions nor organisms resembling *H. ducreyi*. Reasons for this situation are not clear. In spite of the reduced incidence of chancroid we still lack basic information regarding the natural history of this disease. The comparatively rare observation of clinical manifestations of this disease in the

ice was made clear by the community studies, and there is strong desire to build such a center. Much of the planning and sponsorship for a center can be done by community groups with the assistance of the executive secretary of the health referral center, but considerable technical assistance from such agencies as the State and Federal public health services will be needed. Shortly after the community surveys had highlighted rehabilitation and occupational needs of the handicapped, a clinic providing services only for convalescents from a specific illness broadened its program to general convalescent rehabilitation. Also as a result of the surveys, the Goodwill Industries accepted an invitation to operate in Colorado Springs.

In harmony with survey recommendations in Otero County, one of the hospitals established a chronic disease unit and is now interested in expanding that unit. Also, a chronic disease clinic is under development, and there is growing interest in coordination of clinic, home care, and hospital service programs for the chronically ill by the local health department and the hospitals. During or soon after the community studies were begun, news stories reported concerts by a group of "oldster" musicians, fund raising to establish a recreation center for the senior citizens, and entertainments to raise money for television sets and other recreational needs of patients in the new chronic disease unit of the hospital.

Concrete recommendations based on the community studies in Mesa County included these: organization of a rehabilitation service by the medical society, nursing home operators, public health groups, and other interested agencies; medical society, public health department, and public welfare department cooperation in a screening service for placing elderly persons requiring care outside of their own homes; and establishment of a registry of handicapped per-

sons needing assistance of various kinds. The report on the survey of nursing homes recommended finer distinction in definitions of nursing homes, boarding homes, and homes for the aged; appropriate standards for each type of home; more room space and greater privacy in the homes; and better understanding of rehabilitation and recreational needs of persons in the homes. Representative groups have continued their interest in organizing a pilot project to show how a centralized nonsectarian, non-governmental agency guided by a council of professional volunteers can help families solve domestic difficulties before they become major crises. If the project can be financed, special attention will be given during the demonstration period to problems of elderly and chronically ill family members.

In Weld County the community surveys gave impetus to formation of a new adult education class; legislative proposals for a school for the handicapped; new church programs for the chronically ill and the aged; and submission of proposals to the community building committee for a center for the aged in Greeley. Plans for establishing homemaker and home nursing services for the chronically ill and the aged of the county which were proposed at the time of the community surveys are again receiving active sponsorship.

Financial Aid and Technical Guidance

In the long run, the new services and the new ways of providing services which were recommended as a result of the community studies probably will not be beyond the financial means and personnel resources of localities. At present, however, the indications are that some financial aid and considerable technical guidance is needed to implement the recommendations more fully while community interest still is high.

infectious by therapy have played a role in the decline of lymphogranuloma venereum, although this factor cannot be disregarded, since isolation of the infectious agent from tissue does not necessarily indicate infectiousness.

Satisfactory clinical response to therapy is readily achieved by administration of the sulfonamide drugs, chloramphenicol, or the tetracycline antibiotics. Due to the greater cost of the tetracycline antibiotics, the sulfonamide drugs are widely employed in public clinics, and there is no evidence that they are inferior to the tetracycline antibiotics. Both forms of medication have been increasingly employed for the treatment of the anorectal syndrome (12) with gratifying results, frequently making drastic surgical procedures unnecessary.

Granuloma Inguinale

The decline of 78 percent in granuloma inguinale during the past decade is of considerable magnitude. As with chancroid and lymphogranuloma venereum, credit for this decline cannot be given to efforts to identify sources of infection and to administer specific therapy to them. Granuloma inguinale is rarely encountered in sexual contacts, in spite of the chronic nature of the ulcerative lesions and the continued presence of the etiological agent, *Donovania granulomatis*, in the lesions. This suggests a low degree of communicability.

The question has been frequently raised as to whether granuloma inguinale is truly a venereal disease. In spite of its equal distribution between the sexes, there is little epidemiological evidence of its venereal transmission. The possibility that granuloma inguinale represents an autoinfection from a fecal organism has been postulated from time to time (13, 14) and must be considered as a possible explanation of the origin of the disease, at least until better evidence of its sexual transmission is forthcoming.

Diagnosis of granuloma inguinale by demonstrating *D. granulomatis* in smears is a simple procedure. A high degree of success follows therapy with streptomycin, chloramphenicol, or the tetracycline antibiotics. Of interest is the increasing number of reports of granuloma inguinale of the cervix which have appeared in the recent literature (15, 16). This

condition is frequently mistaken for carcinoma, but it has a far better prognosis and responds readily to specific therapy.

Discussion

The downward trend in the minor venereal diseases, chancroid, lymphogranuloma venereum, and granuloma inguinale, during the past decade has been gratifying. It is hoped that this is not a false picture created by the reduction of case-finding programs following the curtailment of funds for venereal disease control during the period 1946-55. If the decline can be assumed to be a real one, it cannot be attributed to vigorous efforts to identify and treat sources of infection since such measures have been the exception rather than the rule. The venereal disease control officers questioned, as well as the writer, are of the opinion that the following factors have contributed to the improved picture:

1. Widespread use of sulfonamide drugs and antibiotics for other diseases may have reduced the reservoir of latent infectious cases of the minor venereal diseases.
2. Improved personal hygiene practices following exposure to infection may have resulted from the educational efforts of the Armed Forces during World War II.
3. Improved socioeconomic circumstances in this country during the past decade may have influenced predisposing factors, such as family breakdown and prostitution.
4. A successful attack has been waged against organized prostitution, which undoubtedly helped to propagate these diseases.

Notwithstanding this improved situation, there are still many gaps in our knowledge of the natural history of the minor venereal diseases.

Summary

The downward trend of the minor venereal diseases, chancroid, lymphogranuloma venereum, and granuloma inguinale, during the decade 1946-55 has been of considerable magnitude although less than that of primary and secondary syphilis. The sharper decline of the latter may reflect more complete epidemiological knowledge, more intensive efforts in contact

female remains to be explained and suggests that it exists in a latent form that is capable of inciting active clinical disease when transmitted to the male. This possibility is further suggested by the report that approximately one-third of Negro hospital patients over 25 years of age had positive skin reactions although most of them denied ever having had ulcerative genital lesions (5). This finding is confirmed by our own experience.

Chemotherapy, employing the sulfonamides, streptomycin, chloramphenicol, or the tetracycline antibiotics, has made the treatment of this disease simple and effective. Failure to respond to such medication should result in questioning of the diagnosis. The sulfonamide drugs and streptomycin are more widely used in view of their lower cost and lack of a tendency to mask a syphilitic infection.

Lymphogranuloma Venereum

The decline of 68 percent in the incidence of lymphogranuloma venereum during the last decade may be considered somewhat remarkable in view of the fact that, as for chancroid, identification of sources of infection has not been a routine practice in most clinics. Furthermore, doubt exists as to whether infectiousness is controlled by therapy, no matter how effective the therapy may be in resolving signs of the disease.

The diagnosis and management of lymphogranuloma venereum are handicapped by the difficulty of identifying the etiological agent by ordinary procedures and by the limitations of the Frei test and the complement fixation test in differentiating past from present infection. According to reports from a number of American cities, Frei tests performed upon adult Negro patients in the wards of general hospitals were positive for 40 to 50 percent (6). The proportion showing positive complement fixation tests is even higher (7), suggesting that the complement fixation test is less specific than the Frei test. Also, a number of workers have reported a lack of correlation between these two tests (8, 9). A high percentage of patients who are positive to both tests deny ever having had any of the typical clinical manifestations of lymphogranuloma venereum.

Trend in number of reported cases of primary and secondary syphilis and the minor venereal diseases, continental United States, 1946-55.

NOTE: Percentage reduction by 1955 derived from the highest figures during the first half of the decade. Basic data from VD Fact Sheet, PHS Pub. No. 341, December 1955, table 5, p. 9.

This suggests that subclinical infection is extremely common and that it probably has constituted a reservoir of infection. Under these conditions, the Frei test and the complement fixation test are of little value in tracing sources of infection. If the decline in reported cases of lymphogranuloma venereum is also reflected in a lower prevalence of positive skin tests and complement fixation tests, these tests may prove to be of greater value in the future in identifying sources of infection.

Another reason for the limited attempts to identify sources of infection of known cases of lymphogranuloma venereum is the uncertainty that specific chemotherapy can make such persons noninfectious (8). Results of a number of studies designed to determine whether the etiological agent of the disease can be isolated from experimental animals or humans subsequent to specific chemotherapy raise considerable doubt that eradication of organisms is achieved with regimens of therapy now in use (10, 11). This leads one to wonder whether factors other than the making of patients non-

AIR POLLUTION

research seminar

On December 18, 1956, in Cincinnati, the Public Health Service convened a national body of investigators in a 3-day seminar for planning research in the causes, effects, and control of air pollution.

Reports of four of the committees of that seminar are presented below in slightly revised form for the information of many who are interested in this work. Reports of the Medical Committee are to be published at a later date. This committee considered mainly the current toxicological studies related to air pollution.

Agricultural Committee

J. T. MIDDLETON, chairman

Air pollution significantly affects the agricultural economy of the country causing damage to animals and vegetation. Many plants respond to a concentration of air pollutants below that usually causing effects in animals, with notable exceptions such as carbon monoxide and hydrogen sulfide. Plants, therefore, may be useful indicators for the detection of air pollutants. The environment and genetic composition determine in large measure the influence of airborne toxicants to such an extent that, at present, it is difficult to prescribe allowable exposure to injurious materials.

The most important air pollutants affecting agriculture requiring additional research are the fluorine-containing compounds. The effect of compounds of bromine, chlorine, and iodine

are recognized, but they are not of immediate practical importance.

Perhaps next in importance are the oxidants, such as ozone, nitrogen oxides, and oxidized organic materials acting as a complex, which are believed responsible for smog damage to plants.

Ethylene and perhaps other low-weight, unsaturated hydrocarbons are believed to produce adverse effects on a variety of agricultural crops, including flowers and other ornamentals.

Miscellaneous organic materials as represented by aromatic complexes and phenolic compounds may have adverse effects on plants and require study.

Sulfur dioxide has long been recognized as an airborne contaminant responsible for specific injury to vegetation, and has been more extensively investigated than any other air pollutant.

Other airborne contaminants include the heavy metals such as mercury, lead, arsenic, and selenium as well as miscellaneous materials

investigation, and more effective therapeutic weapons. This is the consensus of venereal disease control officers questioned regarding the factors believed to play a role in the decline of the minor venereal diseases.

Clearinghouse for Poison Control Centers

A national clearinghouse for poison control centers has been set up by the Public Health Service in line with requests for such services by the American Academy of Pediatrics and the American Public Health Association. A part of the Accident Prevention Program of the Division of Special Services, the clearinghouse will achieve limited operation by midsummer, providing consultative services and case analyses.

Full operations of the new service will include interchanging information among local control centers; stimulating prevention and treatment of poison cases; encouraging research; aiding in the establishment of poison control centers; studying trends in poisoning accidents; and acting as a repository of information.

Staff for the clearinghouse will include a pediatrician, a doctor of pharmacy or a pharmacologist, and an educational specialist.

Other organic compounds such as those found in the aromatic complexes have been implicated in certain instances of damage to vegetation but insufficient information is available to determine the exact nature of the material and its biological effect. It is presumed that a variety of miscellaneous organic materials might likewise be incorporated in this research area, such as growth regulators, fungicides, insecticides, and other agricultural chemicals.

Although mercury has a low vapor pressure, it has been known for some time to be an air pollutant, responsible for plant injury in enclosed spaces. The recent introduction of mercurial paints for use in greenhouses has renewed interest in this problem and emphasizes the need for a reevaluation of this toxicant. Similarly other elements including heavy metals are known to produce adverse biological effects; among these are arsenic, cadmium, lead, and selenium which in the past have been known to occur as air pollutants and should be reviewed periodically and kept in mind as air contaminants of possible importance to agriculture.

Other known air pollutants exemplified by hydrogen sulfide, mercaptans, ammonia, nitric acid, and carbon monoxide, while toxic to plants and animals, are not considered of importance to agriculture except under conditions of gross accidental discharge to the atmosphere.

Though they are recognized as important, this report does not include consideration of radioactive materials.

The air pollution research program in agriculture requires assistance and cooperation of chemical groups in developing needed analytical techniques, engineers for developing corrective and protective devices as well as air handling facilities for specific fumigation studies, meteorologists for assistance in understanding air contaminant dispersion patterns, and medical groups in developing and evaluating bioassay systems for identification and distribution of air pollutants.

The U. S. Department of Agriculture should augment funds available to existing research facilities and management services so that they may actively study from basic and applied points of view the factors affecting the occurrence and result of air pollution upon agriculture. The U. S. Department of Agriculture

with the Public Health Service should support liaison with private, industrial, and public research organizations.

The suggested research needs fall within the disciplines and competence of a large number of existing research organizations and they should be supported and encouraged to attack these problems.

Chemical, Aerosol, and Instrumentation Committee

LEWIS H. ROGERS, chairman

The projects listed below represent the combined efforts of some 30 scientists assembled to outline research areas and projects in the aerosol, chemical, and instrumental field which, in their opinion, require additional research. Taking cognizance of existing projects, the Chemical, Aerosol, and Instrumentation Committee attempted to develop projects not now being carried on. The order of presentation of projects is by subject matter and should not be taken to imply relative ranking according to importance. The group feels that sampling and analyses are such essential tools in all phases of air pollution that work in this field is needed before other problems can be attacked. Specifically, methods must be developed with precisely known accuracies, reproducibilities, and freedom from interference.

It is further recognized that an early start must be made in the study of certain basic problems because of the length of time required for their solution. During the discussions, it became apparent that one of the great needs of the field is for breakthroughs which fundamental research fosters.

In the following list short-, medium-, and long-range projects are designated by the letters S, M, and L, respectively.

Aerosols

Formation of Aerosols

Mechanism of smoke and fume formation including methods of modification (M).

Formation of aerosols during photolysis of polluted atmospheres (M).

Application of the particle-size spectrometer to nucleation studies (S).

Relationship of the composition of aerosols

such as hydrogen sulfide, mercaptans, ammonia, and carbon monoxide.

A description of some of the principal research needs follows.

Research on the effects of fluorides upon plants and animals has shown the gross symptoms resulting from the accumulation of fluorine-containing compounds in animals and plants.

A specific need exists for a study of the mechanism of toxicity and ultimate fate of diverse fluorine-containing compounds in both animals and plants. Both chronic and acute effects of fluoride accumulation are recognized. Particular attention should be paid to studies emphasizing the effect on agriculture of realistic concentrations of fluoride such as those found in industrial areas. Such studies should include the role of fluorides in skeletal development and organ function both for laboratory and farm animals. The effects of fluorides on cellular constituents, uptake, and translocation of fluorides, fate of fluorides in cells, and the nature of resistance and susceptibility in plant material are needed to elucidate the mechanism of action of this important pollutant.

An important area of research also needing attention is the effect of fluorides upon structure and physiological function in animals and plants. Such studies should elucidate the influence of fluorides on assimilation, digestion, and metabolism of the essential nutrients, as well as their effect on lactation, reproduction, and other vital processes in animals. Related studies in plants are required to determine the effect of fluorides on the assimilation and utilization of nutrients, photosynthetic activity, respiration, and enzyme systems, as well as growth and yield. It is also necessary that the degree of foliar necrosis, fluoride content of tissue, and rate of fluoride uptake be related to possible economic plant damage.

Environment and genetic composition materially affect the manifestation of fluoride accumulation in animals and plants. Factors which may affect fluoride toxicity in animals are different levels of nutrition, the presence of other toxicants and diseases, stage of development, pregnancy, and lactation. The response of plants to fluorides under different environments, including varied climatic condi-

tions, fertility, and water relations, requires investigation.

Some study should be made of the alleviation of fluoride effects in animals through management practices and therapeutic treatment.

Protective measures may be developed to reduce the effect of fluorides to sensitive plants.

Although methods for fluorine analysis in plant tissue are reasonably satisfactory at present, analytical methods for fluorides in air and animal tissue are somewhat less satisfactory and require further study.

Research on the influence of sulfur dioxide has been energetically pursued for the past 75 years. The results of these studies have resolved most of the problems affecting agriculture. Those that remain include the effect of sulfuric acid, aerosols, and sulfur dioxide on animals as well as the mechanism of their toxicity singly, together, and in combination with other contaminants.

Oxidants have been recognized as plant damaging agents for more than a decade in certain urban areas, notably in Los Angeles. Although some of the oxidants have been identified as ozone and nitrogen oxides, the agents responsible for most of the injuries to vegetation remain unknown though they are believed to be oxidized organics arising from photochemical reactions in the atmosphere.

There is a real need to develop analytical methods for the identification and determination of oxidants, and to determine the mode of action of the toxicants and their effect on metabolism and growth of plants and possible effects on animals. The gross manifestations of oxidants on plants are generally known.

Organic materials comprise a group of contaminants which have adverse effects upon plants and possibly animals. Ethylene and perhaps other low-weight, unsaturated hydrocarbons may be intimately associated with significant economic damage to orchids, floricultural and ornamental plants, as well as a variety of other agricultural crops. It is believed that ethylene is damaging to some plants at concentrations in parts per billion range, while no effect is recognized in animals at this concentration. A critical need exists for analytical techniques suitable for the detection and monitoring of ethylene and related materials.

for concentrations involved in work with odorants; for example, ultra long path infrared techniques (S).

Interaction of Gases and Aerosols

Photochemistry of organic and inorganic aerosols (M).

Heterogeneous reactions on surfaces (L).

The measurement of adsorption isotherms of pollutants (L).

Determination of the nature of the interaction of adsorbed species with the surface (M).

Meteorology Committee

E. WENDELL HEWSON, chairman

Our assessment of the present status of research on the meteorological aspects of air pollution indicates that progress on a wide front is being made. While very little overemphasis is noted, large areas of underemphasis are apparent.

Although the Meteorology Committee recognizes that it is not fully representative of all meteorologists working in the field, it nevertheless believes that the program of research which follows does outline in broad terms the general avenues along which further progress must be made. To pursue fully any of the particular subjects for research given here might require a number of research projects. We have deliberately kept the statement of each subject general in nature in order not to circumscribe unduly the necessary scope of possible effort. We have with equal deliberation avoided specific recommendations concerning advanced techniques of data transmission, data processing, and so forth, under the assumption that appropriate tools will be used in each case.

The committee recognizes that its recommendations undoubtedly will overlap some of those presented by other committees at this seminar; also, that the solution of many air pollution problems will require the cooperative effort of several groups. Perhaps a Gordon-type conference would be desirable to further the coordination of effort among the several disciplines. (A Gordon-type conference is an informal research review conference held under the auspices of the American Association for the Advancement of Science.)

Apart from the particular research subjects listed, the committee discussed several activities which might enhance the growth of understanding of the meteorology of air pollution problems. Among these might be especially noted: (a) the widest possible dissemination by an appropriate agency of present meteorological knowledge of atmospheric dispersion; (b) compilation and review of knowledge of the various aspects of air pollution meteorology, augmented by a broad reevaluation of practical applications and incorporated into a monograph summarizing the field and indicating research requirements; (c) further development of a centralized national network to collect data on air quality which is directed toward better establishing the trend of air pollution; and (d) evaluation of available methods of meteorological measurements for their applicability to community air pollution studies. With respect to items (a) and (b) above, it is recognized that knowledge of recent developments in the field is not shared widely, even among practicing meteorologists. The committee welcomes the fact that some pertinent information previously classified may soon become generally available.

Recommended Research

General

Design of a major air pollution investigation.

On the basis of the above design, organization of a comprehensive and definitive urban area study.

Instrumentation

Development of simple yet adequate meteorological instrumentation and methods of analysis of resulting data.

Development of inexpensive tracer techniques for meteorological use.

Model Studies

Development of scale model techniques for simulating atmospheric diffusion processes as related to area sources.

Development of methods for simulating terrain influences on air flow patterns.

Physical Processes

Studies of nucleation, atmospheric transmission, and absorption of solar radiation.

to that of the feed material; for example, relationship of particulate sulfate to sulfur dioxide (L).

Changes accompanying the aging of particulate pollutants (L).

Development and evaluation of devices for the controlled production of aerosols, such as are techniques and furnace methods (S).

Physical Properties of Aerosol Systems

Correlation of surface area with other properties (M).

Effect of aerosol shape on light scattering (M).

Dynamics of movement of particles in large volumes (M).

Development and evaluation of tracer techniques. Examples are:

Magnetic materials (S)

Natural germanium in coal, vanadium in oil (S)

Micro-organisms (S)

Automatic counting methods (S)

Sampling and Analysis

Behavior of particles approaching collecting surfaces (S).

Behavior of thermally conducting particles in a thermal gradient (S).

Development and evaluation of stack sampling equipment, such as high temperature aerosol cameras or counters, and particle size spectrometers (S).

Development and evaluation of new collectors, such as isokinetic samplers and wet collectors (S).

Application to aerosol analysis of special techniques. Examples are:

Infrared reflectance (S)

X-ray diffraction (S)

Chromatography (S)

Electrophoresis (S)

Interlaboratory comparison and statistical evaluation of analytical methods (M).

Gases

Gaseous Reactions

Photolysis of organic compounds in oxygen (M).

Rates and mechanism of elementary reactions in the photolysis of nitrogen dioxide with hydrocarbons in oxygen (M).

Photochemical reactions of effluents from known pollution sources, such as auto exhausts and incinerators (M).

Thermal reactions between ozone and unsaturated organic compounds (M).

Rates and mechanism of reactions occurring during incomplete combustion (L).

Nitrogen fixation in combustion equipment (M).

Sampling and Analysis

Collection of specific contaminants by means such as ion exchange resins and molecular sieves (S).

Development and evaluation of adsorption techniques for the concentration of air pollutants (M).

Development of techniques for the removal of specific substances such as water and carbon dioxide (S).

Development and evaluation of methods and equipment for low temperature condensation of pollutants (S).

Development of specific economical analytical methods suited to special needs. Examples are:

Ozone (S)

Acrolein (S)

Halogenated carbonyl compounds in the p.p.b. range (S)

Aldehydes (S)

Oxides of nitrogen (S)

Differentiation of sulfur compounds (S)

Development of bioassay methods such as enzymatic reactions and organism toxicity (S).

Interlaboratory comparison and statistical evaluation of analytical methods (M).

Development and evaluation of special non-specific analytical techniques. Examples are:

Microbiological indicators for physiological effects (S)

The vibrating reed surface potential apparatus (S)

Special mass spectrometric techniques: for example, to determine parent masses and/or negative ions (S)

Phosphorescence spectra and decay times for the identification of polycyclic hydrocarbons (S)

Other physical techniques including NMR, EMR, and microwave spectrometry (S)

Development of special analytical techniques

source through modification of the process or materials handled.

2. Control of contaminants at the source by suitable devices.

It is the opinion of the committee that the needed engineering research should be in two categories:

1. Problems for which early or prompt solution is desirable and practical. Included in this category are:

a) Control of pollutants associated with effluents from combustion operations, namely, particulates, certain acid gases such as oxides of sulfur and nitrogen, and hydrocarbons.

b) Specific area control problems associated with the effluents from the petroleum refining industry, the metallurgical industry, and the chemical industry.

2. Problems of a less urgent priority.

The general research program, as discussed by the committee, considered two divisions of these categories, namely, field studies and laboratory investigations.

It became apparent in discussing engineering research that instrumentation plays an important role, both in identification of a source and its magnitude and in the evaluation of control equipment. Some of the needed engineering research requires the prior development of suitable instrumentation.

Instruments urgently needed for research and control include:

a) An instantaneous quantitative gas spectrum analyzer.

b) Particle-size analyzer for the 0.01 to 0.3 micron range.

c) A rapid mass distribution analyzer for particulates in gas streams.

Also needed are the following:

a) Simple fluoride gas-aerosol discriminator.

b) Simple stack effluent weight analyzer.

c) Light scattering analyzer for solids in gas streams.

Problems Needing Prompt Solution

Field

Pollution of the atmosphere from solid fuel combustion processes, we believe, possesses such magnitude and characteristics that a qualitative

and quantitative assessment of these contaminants is necessary. This is best accomplished through a fundamental field investigation of:

1. The characteristics of the effluents resulting from solid fuel combustion processes.

2. The determination of factors affecting the formation of oxides of nitrogen.

The solid fuel process effluent characteristic evaluation should include the determination of physical characteristics of the solids and the assay of the chemical composition of the liquid and gaseous contaminant discharges.

Laboratory

Test Gas and Aerosol Preparation

Preparation of gas and aerosol simulants is an important aspect of the development and appraisal of engineering devices for control of air pollution. A fundamental investigation of means and methods of preparing gases to simulate atmospheres and processes is desirable and a similar approach to the preparation of aerosols of various physical properties, such as shape, size, specific gravity, and surface characteristics, is essential. Such aerosol preparation information is fundamental to the study of the behavior of aerosols both within quiescent atmospheres and in dynamic gas streams and in the study of the performance of various mechanisms for removal of aerosols.

Studies of Process Modifications

One of the important problems in air pollution control from a fundamental standpoint is to investigate the sources of air pollution as related to the industrial process. We believe that essential studies in modification of processes and materials handling, from a basic formation of contamination viewpoint, are of major importance. Modification or alteration of a process so as to eliminate the contamination obviously eliminates the need for further control equipment, and may contribute substantial economies. We believe that there are many unrealized opportunities for attack upon air pollution by this strategy.

Treatment of Gaseous Contaminants

Additional investigation is needed in the study of the absorption, adsorption, and chemical conversion of gases in such concentrations

Investigation of self-purification processes in the atmosphere.

Dispersion

Fundamental research on atmospheric turbulence and diffusion.

Study of persistent atmospheric conditions which tend to produce severe pollution.

Development of pollution potential indexes.

Investigation of the structure of the lower atmosphere in relation to basic diffusion processes, especially in urban areas.

Research on pollution from remote sources.

Theoretical studies of diffusion from large area and volume sources.

Study of the influence of heat sources and sinks on air pollution patterns.

Development of methods of interpreting climatological data for air pollution studies.

Investigation of the application of the methods of multiple-time series analysis, information theory and general stochastic procedures to the prediction of the probability distribution of the concentration of atmospheric pollution at a point.

Engineering Committee

LESLIE SILVERMAN, chairman

The objectives of engineering research in air pollution are to investigate, develop, and appraise mechanisms, devices, and processes for the control of air pollution and to define, measure, and evaluate air contamination from all sources. Control in this context encompasses the prevention of air contamination which may create a nuisance and which may be injurious to property, vegetation, animals, and human health and welfare.

Engineering research in the area of air pollution inherently includes economic considerations of control or elimination of contamination at the source. Many occurrences of air pollution result from a failure to consider those factors influencing air pollution. In this regard may be cited the fact that many otherwise well-designed processes consider only the product requirement and operational efficiency rather than the contaminants that may be discharged to the atmosphere as a result of the process. It is the opinion of the Engineering Committee

that this phase of the problem should be directed to the attention of those engineers who are responsible for process design.

The committee is aware of the fact that many of the problems now considered as critical can be solved without further research through the application of well-known and well-established control principles. However, it should be emphasized that one of the major phases of engineering research must be directed toward economic methods of control.

Considerable emphasis in air pollution control pertains to the effects of contaminants on property and vegetation susceptible to direct economic evaluation. The committee has considered these effects in addition to the health aspects of the problem.

One of the fundamental needs is perspective in consideration of the entire problem. This can be obtained only by giving consideration to future requirements while appraising present research in terms of its potential application to existing problems. The committee recognizes the value of such creative thinking in regard to engineering investigation in the air pollution area and feels that it should not be neglected in establishing any long-range research planning. Since the solution of many of the problems in air pollution requires various technical competencies in the engineering field as well as an engineering perspective toward the evaluation of source characteristics and control requirements, it is felt that the engineer, per se, is particularly adapted to the assessment of the basic problem.

The committee recognizes the essential need for definition of the air pollution problem in terms of relationships between pollutants and ill effects, whether in terms of human or animal response, vegetation injury, or material damage. It is further recognized that the rate of progress in solving air pollution problems is dependent to a considerable degree upon the rate at which these relationships can be established.

There are two fundamental engineering approaches to the problem of control of contamination in the atmosphere, and emphasis in research should be directed toward both:

1. The elimination of the contaminant at the

STATEMENT

*By the United Nations Scientific Committee
on the Effects of Atomic Radiation*

Responsibilities of the Medical Profession in the Use of Ionizing Radiation

THE UNITED NATIONS General Assembly, being aware of the problems in public health that are created by the development of atomic energy, established a Scientific Committee on the Effects of Atomic Radiation at its tenth session, 1955-56. This committee considers that one of its most urgent tasks is to collect as much information as possible on the amount of radiation to which man is exposed today, and on the effects of this radiation. Since it has become evident that radiation due to diagnostic radiology and to radiotherapy constitutes a substantial proportion of the total radiation received by the human race, the committee considers it desirable to draw attention to information that has been obtained on this subject.

Modern medicine has contributed to the control of many diseases and has substantially prolonged the span of human life. These results have depended in part on the use of radiation in the detection, diagnosis, and treatment of disease. There are, however, few examples of scientific progress that are not attended by some disadvantages, however slight. It is desirable therefore to review objectively the possible present or future consequences of increased irradiation of populations which result from these medical applications of radiation.

It is now accepted that the irradiation of human beings, and particularly of their germinal tissues, has certain undesirable effects. While many of the somatic effects of radiation may be reversible, germinal irradiation normally has an irreversible and therefore cumulative effect. Any irradiation of the germinal tissues, however slight, thus involves genetic damage which may be small but is nevertheless real. For so-

matic effects there may however be thresholds for any irreversible effects, although if so these thresholds may well be low.

The information so far available indicates that the human race is subjected to natural radiation, as well as to artificial radiation due to its medical applications, to atomic industry and its effluents, and to the radioactive fallout from nuclear explosions. The radiation due to natural sources has been estimated to cause between 70 and 170 millirem of irradiation to the gonads per annum in most parts of certain countries in which it has been studied, although higher values are found locally in some areas (1). The committee is aware of the potential hazards that both natural and artificial radiation involve, and it is collecting and examining information on these subjects.

The amount of radiation received by the population for medical purposes is now, in certain countries, the main source of artificial radiation and is probably about equal to that from all natural sources. Moreover, since it is given on medical advice, the medical profession exercises responsibility in its use.

The committee appreciates fully the importance and value of the correct medical use of radiation, both in the diagnosis of a large number of conditions, in the treatment of many such diseases as cancer, in the early mass detection of conditions such as pulmonary tuberculosis, and in the extension of medical knowledge.

Moreover, it appreciates fully the contribution of the radiological profession, through the International Commission on Radiological Protection in recommending maximum permissible levels of irradiation (2). As regards

that they are a nuisance or hazard. Such studies should include basic approaches to control of acid gases, including oxides of sulfur and nitrogen, and to the elimination of hydrocarbon vapor emissions. Emphasis should be placed on development of economically feasible methods and processes.

Tabulation of Needed Research

Field Investigations

Process Evaluation—Effluents

1. Compilation of characteristics and rates of effluent emissions.
2. Assessment of internal combustion engine emissions (urgent).
3. Determination of solid fuel process characteristics (urgent).
4. Appraisal of nitrogen oxide formation (urgent).
5. Relationship between transparent and opaque particulates.

Process Evaluation—Modifications

General investigation of process modifications for pollution control.

Control Equipment Evaluation

1. Establishment of incinerator design criteria.
2. Evaluation of filter devices.
3. Evaluation of inertial separators.
4. Determination of electrostatic precipitator performance.

Community Survey Techniques

1. Comparison of hourly dustfalls.
2. Acquisition of particle size data at ground level.

Laboratory Studies

Source Simulation

1. Preparation of test gases and aerosols (urgent).
2. Determination of properties, behavior, and methods of specification of aerosols (urgent).
3. Investigation of sampling methods (isokinetic).

Principles of Gas and Aerosol Control

1. Studies of process modifications (urgent).
2. Fundamental studies on filtration mechanisms.
3. Development of high temperature filter media.
4. Further studies on electrostatic phenomena.
5. Evaluation of droplet-type scrubbers.
6. Exploratory studies of less common mechanisms.
7. Fundamental treatment of gaseous contaminants (urgent):
 - a) Absorption and adsorption of SO_2 and SO_3 at low concentrations.
 - b) Oxides of nitrogen treatment and control.
 - c) Conversion studies including catalytic and noncatalytic combustion.

A New Device for Sputum Testing

A device that makes sputum testing for tuberculosis safer has been developed by a Veterans Administration bacteriologist.

A new type of paint shaker was modified for use as an agitator of sputum specimens by Abraham L. Rosenzweig at McGuire Veterans Administration Hospital in Richmond, Va. The device has been adopted by the 173 hospitals of the Veterans Administration.

During the vigorous agitation required in homogenizing viscous material, the standard agitator had to be anchored, and could not be secured easily under a safety hood to protect workers from live germs.

Because the main part of the new device does not vibrate, it reduces the potential danger from tuberculosis germs released by vibration into the air of the laboratory.

those whose occupation exposes them to radiation, the establishment of these levels depends on the view that there are doses which, according to present knowledge, do not cause any appreciable body injury in the irradiated individual; and also on the consideration that the number of people concerned is sufficiently small for the genetic repercussions upon the population as a whole to be slight. Whenever exposure of the whole population is involved, however, it is considered prudent to limit the dose of radiation received by germinal tissue from all artificial sources to an amount of the order of that received from the natural background radiation.

It appears most important, therefore, that medical irradiations in any form should be restricted to those which are of value and importance, *either in investigation or in treatment*, so that the irradiation of the population may be minimized without any impairment of the efficient medical use of radiation.

The committee is consequently anxious to receive information through appropriate governmental channels as to the methods and the extent by which such economy in the medical use of radiation can be achieved, both by avoiding examinations which are not clearly indicated and by decreasing the exposure to radiation during examinations, particularly if the gonads, or the fetus during pregnancy, lie in the direct beam of radiation. It seeks, in particular, to obtain information as to the reduction in radiation of the population which might be

achieved by improvements in instrument design, by fuller training of personnel, by local shielding of the gonads, by choosing appropriately between radiography and fluoroscopy, and by better administrative arrangements to avoid any necessary repetition of identical examinations.

The committee also seeks the cooperation of the medical profession to make possible an estimate of the total radiation received by the germinal tissue of the population before and during the childbearing age. It considers it to be essential that standardized methods of measurement, of types at present available, should be widely used to obtain this information and it emphasizes the value of adequate records, maintained by those using radiation medically, by the dental profession, and by the *responsible organizations in allowing such radiation exposure to be evaluated*. The committee is convinced that information of this type will make it possible to decrease the total medical irradiation of the population while preserving and increasing the true value of the medical uses of radiation.

New Benefits for Disabled Children

A new type of social security benefit was paid for the first time in February 1957 to qualified workers' disabled children over the age of 18. Authorizing these benefits is a 1956 amendment to the Social Security law. Payments are provided for disabled children of retired or deceased workers after the children pass 18 years of age, if those children are unable to work and were disabled before age 18.

Nearly 3,000 applications for these insurance benefits were processed by the Bureau of Old-Age and Survivors Insurance during 1957. Estimated to be eligible for the payments during 1957 are more than 20,000 persons. They may receive benefits back to January 1957 if they apply through their local social security offices before the end of January 1958. After this date, benefits will not be paid retroactively for more than 12 months.

Implications of Recent Viral Studies

By ROBERT J. HUEBNER, M.D.

SOON AFTER the bacterial causes of respiratory illnesses were delineated, it was noted that certain filterable viruses also caused such diseases. When the viruses of influenza, psittacosis, and Q fever finally became known a few years ago, it seemed that the rest of the respiratory disease problem would be solved without difficulty. Only three more agents, the viral causes of the "common cold," of acute respiratory disease (febrile catarrh), and of primary atypical pneumonia remained to be found.

However, the number of viruses that might be involved was not realized. Indeed, quite recently, River's textbook, *Viral and Rickettsial Infections of Man*, listed only about 60 viral agents. Today, only a few years later, with the widespread application of new techniques now available in virology, more than 65 additional, newly recognized viruses have been demonstrated in man. One would be justified, therefore, in thinking that we now know much more about the viral causes of respiratory disease. True, we do know a little more. But while isolating viruses is no longer so difficult, the eventual solution of the problem of respiratory disease is more complex.

The "new" viruses are found with great frequency in the upper part of the respiratory tract and in the enteric tract. They have been

called "viruses in search of disease." Most of them are lumped under arbitrarily selected family designations such as Cocksackie, ECHO, and adenoviruses (APC-RI viruses); in addition, there are viruses such as the Sendai virus from Japan, various exanthema viruses including those reported by Neva and Rake, the virus of cytomegalic inclusion disease, and many other completely unclassified agents.

The discovery of these new agents has led to considerable progress in the etiological delineation of a number of common illnesses. It is well established that 6 to 8 of the group A Cocksackie viruses cause herpangina, a specific and very common upper respiratory disease of children with fever and other systemic involvement. Group B Cocksackie viruses have been shown to cause not only epidemic pleurodynia, but also nonbacterial meningitis, which until recently was probably most often diagnosed as nonparalytic poliomyelitis. Some of the viruses in the ECHO group, particularly type 6, have also been incriminated in the etiology of nonbacterial meningitis. The recently discovered adenoviruses cause febrile respiratory and ocular illnesses. Acute respiratory disease (ARD) of military recruits is known to be caused by at least three adenovirus serotypes. Other serotypes cause a newly described illness, pharyngoconjunctival fever (Greeley's disease), and still other types have been incriminated in the etiology of simple febrile pharyngitis and simple conjunctivitis. One type has been shown to be regularly associated with epidemic keratoconjunctivitis.

Polyvalent Vaccines

One of the more obvious opportunities provided by the easy demonstration and cultiva-

Bacterial Allergies

Of course, in addition to these rather unsubstantial ailments, there is a definite problem of specific microbial disease of nasal and pharyngeal areas, much of which is the consequence of acute infection. Here, again, it is pertinent to ask how much of recurrent respiratory illness might be due to bacterial allergies. Another hypothesis which possibly should be given more consideration is that some of the latent viruses, such as adenoviruses, persisting in the tissues of most respiratory tracts may become activated by undetermined factors and cause recurrent inflammation of the mucous membranes in those areas.

As in the case of recurrent herpes infection, such hypothetic occurrences might be expected to result in less severe illnesses than those produced by the primary infection. We have hesitated to suggest that reactivation of the adenovirus agents, demonstrably present in the nasopharyngeal passages of most persons, might represent a possible cause of common colds, since in most of those from whom such agents are recovered during afebrile illness there is generally no increase in adenovirus antibodies.

However, recurrent herpes virus infections also are not followed by any measurable antibody response. In view of the fact that adenoviruses have been isolated on several occasions from the respiratory secretions of persons with afebrile respiratory illnesses or typical common colds, the hypothesis that colds may be due to reactivation of these agents may possibly have been discarded too readily. After all, the activation of latent agents is not a rare or unknown phenomenon. The psittacosis virus in its natural host may be regarded as an agent essentially latent with the capacity of being activated at intervals. It is precisely during these exacerbations of infection and illness that birds become an important source of infection to other birds and to man.

"Unmasking" Viruses

The notable progress in the definition of acute viral diseases through application of new virological techniques is sure to be followed by more intensive application of these techniques. The development of even better ones offers

promise of further progress in the study of the varied causes of acute and chronic human disease. It seems inevitable, as new and different tissues are introduced and utilized in tissue culture, that many more viral agents will be encountered. The long-term culture of normal or abnormal tissues, which is essentially a simple, if newly applied, technique for isolating viruses, may possibly turn out to be of even greater importance.

Several years ago, Dr. Wallace P. Rowe and I described viruses emerging from the epithelial cell outgrowths of human adenoids. These agents, which had a special tropism for human epithelial cells, were the first representatives of the adenovirus family of viruses to be recognized; they were found in the epithelial cells of most adenoids and tonsils, generally after 18 to 30 days of continuous culture of the original cells. They could not be demonstrated in such tissues by conventional methods of virus isolation. Serotypes 1, 2, and 5, the most commonly encountered, were subsequently shown to be acquired most often in early childhood, yet they are unmasked from the adenoids of older children and adults quite as readily as from those of infants. There is little question that following primary infection these viruses become latent or chronically infecting particles. More recently, we also succeeded in unmasking the salivary gland virus, the cause of cytomegalic inclusion disease, from the fibroblastic outgrowth of adenoids.

This agent, which was only recently first isolated in tissue culture by Dr. Margaret Smith, has long been a collector's item among pathologists who specialize in recognizing its existence in fixed tissue taken at autopsy. Subsequently, our research group and Dr. Thomas Weller at Harvard also demonstrated the agent in adenoid tissues, in biopsy of liver tissue, and from the urine of living persons, some with evidence of cytomegalic inclusion disease.

With the development of serologic techniques for studying this agent, it now appears that the salivary gland virus is a widespread infectious agent in man, approaching almost total infection in older age groups. We have also occasionally picked up herpes virus in tissue cultures of adenoid cells, and it is noteworthy that we succeeded in isolating three separate viruses,

tion of so many new viruses is the preparation of effective prophylactic vaccines for the prevention of some of the very common nonfatal illnesses. Last year, our group at the National Institute of Allergy and Infectious Diseases, Public Health Service, reported a successful test of an adenovirus vaccine in which we were able to show good protection of vaccinated volunteers against experimentally induced attacks of pharyngoconjunctival fever.

At the present time Dr. Joseph Bell and I, in cooperation with U. S. Navy Medical Research Unit No. 4, are engaged in field trials of a commercially produced polyvalent vaccine containing adenoviruses types 3, 4, and 7. These studies are being carried out at the Great Lakes Naval Training Station, Great Lakes, Ill., and will eventually embrace observations on some 16,000 military recruits. Preliminary analysis of data now available show that in the vaccinated recruits there is at least a 50 percent reduction from expected rates of acute respiratory disease. These results are encouraging, not only because it may now be possible to prevent some of the more severe respiratory viral diseases, but also because they suggest that similar vaccines can be made, if it proves desirable, against representatives of the other new groups of agents, such as Cocksackie, ECHO, and exanthema viruses.

What bearing do these new developments have on the total problem of acute respiratory disease? Unfortunately, despite the notable progress in finding the etiological agents of respiratory diseases, the cause of most of them must apparently still be found, particularly the causes of those generally termed "common cold."

Of course, a good deal depends on what is meant by "common cold." To begin with, it is not the only term in popular use. "Virus X" has some obscure yet special meaning to some lay groups. Physicians in many areas use the terms "virus infection" or "virus" to characterize essentially unexplainable illnesses. It seems only a matter of time before a new virus, known as "virus X²" will emerge.

In my opinion, the term "common cold" requires considerable analysis. Recent work with volunteers has convinced some of us that a large number of so-called common colds are

not due to viruses but to other factors, not the least of which are of psychosomatic origin. The nasopharyngeal symptoms of the common cold have occurred in a high proportion of volunteers, whether or not they received virus-containing or virus-free materials. Evaluation of some of these volunteers showed in psychological tests a rather significant association of high gullibility scores with complaints of upper respiratory illness. Although more work will be necessary to put these observations on a solid basis, our findings in numerous volunteer studies indicate that susceptibility to suggestion represents a more powerful inciter of "runny" noses than any virus which we have as yet discovered.

Well-controlled evaluations of the prophylactic value of common cold vaccines and the therapeutic effects of antihistamines have shown that innocuous control materials have remarkable effects in the apparent prevention and cure of colds. More significant perhaps than the fact that these control materials seemed to perform quite as well as the presumably active materials being tested was the fact that 50 percent or more of persons receiving simple saline vaccines and sugar pills in double-blind studies regularly reported prevention, modification, or cure of colds by these innocuous substances.

Loosli's recent studies of the occurrence of common colds in industry showed that a comparatively small number of industrial workers contributed most of the absenteeism attributable to common colds. It is difficult for a virologist to conceive of viruses behaving in so illogical a manner. I might add, as the father of 8 children, 6 of whom are in school, that I cannot escape the feeling that there is very definite association of "colds" with Monday mornings. It is difficult to think of even "virus X" as causing these Monday morning episodes. Perhaps there is a "Monday morning" virus. However, I think the Victorians had a better word for it. The expression "she is indisposed" occurs time and time again in Victorian literature. It is possible, of course, that occasionally this truly represented a "viral indisposition," but I wonder whether such a virus could be grown even with modern tissue cultures or that present or future miracle drugs could cure it.

Surveillance of Poliomyelitis in the United States in 1956

COLLECTION and dissemination of epidemiological data on the safety and effectiveness of poliomyelitis vaccine are the primary functions of the National Poliomyelitis Surveillance Program, which was established in April 1955 at the Communicable Disease Center of the Public Health Service. These data are summarized and distributed currently in the mimeographed Poliomyelitis Surveillance Reports, which are available to all persons with responsibility in the control of poliomyelitis. A review of information collected in 1955 has been published (1). The present report summarizes the data for 1956.

As part of the surveillance program a clearinghouse of information is maintained in the Poliomyelitis Surveillance Unit, Communicable Disease Center. There is constant mutual exchange of data between the unit and State and local health departments, virus diagnostic laboratories, the National Foundation for Infantile Paralysis, and others. More than 40 officers of the Communicable Disease Center's Epidemic Intelligence Service contribute to this activity.

This report was prepared by the staff of the Poliomyelitis Surveillance Unit: Dr. Neal Nathanson, chief; Dr. William Jackson Hall, assistant chief; Dr. Lauri D. Thrupp, epidemic intelligence service officer; and Helen Forester, statistician. The unit is part of the Epidemiology Branch (of which Dr. Alexander D. Langmuir is chief), Communicable Disease Center, Public Health Service, Atlanta, Ga. The paper was presented at a meeting of representatives of State medical societies, called by the American Medical Association, in Chicago. January 26, 1957.

Poliomyelitis Incidence in 1956

During 1956 a total of 15,400 cases of poliomyelitis were reported to the National Office of Vital Statistics, Public Health Service, a rate for the United States of 9.2 cases per 100,000 population. This is the lowest rate reported since 1947. Marked annual variations in poliomyelitis incidence are apparent from a comparison of rates for the years 1910 through 1956 (fig. 1) and from a comparison of poliomyelitis incidence by weeks for 1956 with the years 1946 through 1955 (fig. 2). Because of these wide annual variations in incidence, it is not yet possible to attribute the low incidence reported in 1956 to the widespread, although incomplete, use of poliomyelitis vaccine. Further decreases in incidence over the next several years may be of greater significance.

The 1956 incidence rates for six geographic regions, with median rates for the period 1951-55, appear in table 1. The highest regional rates in 1956 were in the Southwest, the South Central, and the North Central States; these same regions also had the highest 5-year median rates. Lowest 1956 rates and lowest 5-year median rates were reported for the Northeast and the Southeast.

For individual States a similar comparison of 1956 rates with 5-year median rates appears in figure 3. (The number of cases reported in 1956 for each State, by paralytic status, is given in table 2.) The four States with the highest 1956 rates were Utah, Iowa, Louisiana, and Illinois, in that order. None of these States experienced particularly low median rates for the previous 5 years. The high 1956 incidence in Utah reflects an epidemic in Salt Lake City and the surrounding area. The cases reported

an adenovirus, the salivary gland virus, and the herpes virus from the epithelial and fibroblastic outgrowth of the adenoid of one person.

The recent report that many different viruses have been isolated from monkey renal tissues which had been used in the production of poliomyelitis vaccine represents another interesting example of the "unmasking" of viruses from cells. The many ideas implicit in new information of this sort cannot be developed here. Perhaps the most important point is that whole areas of acute and chronic human disease, unexplained except that they are assumed to be noninfectious in origin, must be reexamined in the light of the new concepts concerning the nature and consequences of viral infections.

The simple fact that from two tissues, the *human adenoid of man and the kidney of the monkey*, 25 or more immunologically distinct viruses have been unmasked, supports the con-

cept that the human cell itself must be regarded as having a considerable viral flora. Should this concept, which of course is not new to those working with bacterial and plant viruses, prove to be true, it cannot fail to have tremendous influence upon future investigations into the cause of human disease, regardless of its apparent lack of connection with microbial infection. For instance, a virologist can hardly conceive how human cells could remain uninfluenced by the viruses growing within them, and, furthermore, how such experiences could fail to be an important factor in the malfunction and erosion of cells which the clinician calls "degenerative or chronic disease."

It seems to me only a matter of time until the clinician and virologist find themselves collaborating not only in an effort to cure sick cells but also in attempting to prevent such occurrence.

Board of Regents of the National Library of Medicine

Dr. Worth B. Daniels, clinical professor of medicine at Georgetown University, was elected chairman of the Board of Regents of the National Library of Medicine. At its first meeting, March 20, 1957, the 17-member board also elected as vice chairman Dr. Champ Lyons, professor of surgery, University of Alabama Medical College, and as secretary of the board, Lt. Colonel Frank B. Rogers, library director. The board is authorized by the 84th Congress to advise the Surgeon General of the Public Health Service on the policy of the library.

Ten board members are appointed by the President from the fields of science, medicine, and public affairs, and seven are ex officio members in Government service. The chairman is elected from among the appointed members.

Other appointed members of the board are: Dr. Basil G. Bibby, professor of dentistry, University of Rochester; Dr. Jean A. Curran,

Bingham Associates Fund, Boston; Dr. Michael E. Debakey, professor of surgery, Baylor University; Dr. Thomas Francis, Jr., professor of epidemiology, University of Michigan; Miss Mary Louise Marshall, professor of medical bibliography, Tulane University; Dr. I. S. Ravdin, professor of surgery, University of Pennsylvania; Dr. Benjamin Spector, professor of anatomy, Tufts University; Dr. Ernest Volwiler, president, Abbott Laboratories.

Ex officio members are: Dr. Leroy E. Burney, Surgeon General, Public Health Service; Major General S. B. Hays, Surgeon General, U. S. Army; Rear Admiral B. W. Hogan, Surgeon General, U. S. Navy; Major General D. C. Ogle, Surgeon General, U. S. Air Force; Dr. William S. Middleton, chief medical director, Veterans Administration; Dr. John T. Wilson, assistant director for biological and medical sciences, National Science Foundation; and Dr. L. Quincy Mumford, Librarian of Congress.

Surveillance of Poliomyelitis in the United States in 1956

COLLECTION and dissemination of epidemiological data on the safety and effectiveness of poliomyelitis vaccine are the primary functions of the National Poliomyelitis Surveillance Program, which was established in April 1955 at the Communicable Disease Center of the Public Health Service. These data are summarized and distributed currently in the mimeographed Poliomyelitis Surveillance Reports, which are available to all persons with responsibility in the control of poliomyelitis. A review of information collected in 1955 has been published (1). The present report summarizes the data for 1956.

As part of the surveillance program a clearinghouse of information is maintained in the Poliomyelitis Surveillance Unit, Communicable Disease Center. There is constant mutual exchange of data between the unit and State and local health departments, virus diagnostic laboratories, the National Foundation for Infantile Paralysis, and others. More than 40 officers of the Communicable Disease Center's Epidemic Intelligence Service contribute to this activity.

This report was prepared by the staff of the Poliomyelitis Surveillance Unit: Dr. Neal Nathanson, chief; Dr. William Jackson Hall, assistant chief; Dr. Lauri D. Thrupp, epidemic intelligence service officer; and Helen Forester, statistician. The unit is part of the Epidemiology Branch (of which Dr. Alexander D. Langmuir is chief), Communicable Disease Center, Public Health Service, Atlanta, Ga. The paper was presented at a meeting of representatives of State medical societies, called by the American Medical Association, in Chicago. January 26, 1957.

Poliomyelitis Incidence in 1956

During 1956 a total of 15,400 cases of poliomyelitis were reported to the National Office of Vital Statistics, Public Health Service, a rate for the United States of 9.2 cases per 100,000 population. This is the lowest rate reported since 1947. Marked annual variations in poliomyelitis incidence are apparent from a comparison of rates for the years 1910 through 1956 (fig. 1) and from a comparison of poliomyelitis incidence by weeks for 1956 with the years 1946 through 1955 (fig. 2). Because of these wide annual variations in incidence, it is not yet possible to attribute the low incidence reported in 1956 to the widespread, although incomplete, use of poliomyelitis vaccine. Further decreases in incidence over the next several years may be of greater significance.

The 1956 incidence rates for six geographic regions, with median rates for the period 1951-55, appear in table 1. The highest regional rates in 1956 were in the Southwest, the South Central, and the North Central States; these same regions also had the highest 5-year median rates. Lowest 1956 rates and lowest 5-year median rates were reported for the Northeast and the Southeast.

For individual States a similar comparison of 1956 rates with 5-year median rates appears in figure 3. (The number of cases reported in 1956 for each State, by paralytic status, is given in table 2.) The four States with the highest 1956 rates were Utah, Iowa, Louisiana, and Illinois, in that order. None of these States experienced particularly low median rates for the previous 5 years. The high 1956 incidence in Utah reflects an epidemic in Salt Lake City and the surrounding area. The cases reported

from Iowa undoubtedly include many cases of nonpoliomyelitis viral meningitis since less than 10 percent of the cases were reported as paralytic and since isolations of Coxsackie virus were reported from outbreaks in four areas of the State. Only in Louisiana did reported incidence exceed the 5-year median; high endemic rates were reported in several areas of this State. The largest concentrated outbreak during 1956 occurred in Chicago. More than 1,100 cases were reported, a rate of about 30 per 100,000.

Vaccine Safety

Surveillance of vaccine safety is based primarily on analysis of poliomyelitis cases occurring within 30 days of a poliomyelitis vaccination. Cases of this kind are routinely reported to the Poliomyelitis Surveillance Unit by all State and Territorial health departments. In addition, this phase of the program includes collection of some data on possible reactions to the vaccine.

Poliomyelitis Following Vaccination

With more than 70 million inoculations of vaccine given during 1956 and with considerable amounts of vaccine used in high-incidence areas, it is clear that by coincidence alone a large number of cases would be expected to occur shortly after vaccination. Thus, the purpose of surveillance of vaccine safety

is to determine whether coincidence is an adequate explanation for all the cases occurring shortly after vaccination. It must be recognized, now that vaccine is frequently used during periods of high incidence, that epidemiological methods may not detect the occurrence of small numbers of vaccine-related poliomyelitis cases.

Cases are currently analyzed for (a) excessive frequency of association with individual lots of vaccine, (b) concentration within the 4- to 11-day period of the intervals between inoculation and onset, and (c) correlation between sites of inoculation and sites of first paralysis. These were the distinguishing epidemiological characteristics of the cases in 1955 associated with vaccine manufactured by Cutter Laboratories (1).

During 1956, 500 under-30-day cases were reported, 229 of which were paralytic. (This total does not include a group of more than 300 cases in Chicago, which will be discussed in a later section of this paper.) Comparison of these 229 paralytic cases with the 70 million doses of vaccine administered gives an average ratio of about 1 paralytic case for every 300,000 inoculations. Classification of cases according to manufacturers and lot numbers of the vaccine used showed that only 5 lots distributed in 1956 were associated with more than 5 paralytic cases, while half (67) of the lots were not associated with any paralytic cases. Analysis of the 5 lots associated with more than 5 paralytic

Figure 1. Annual poliomyelitis incidence rates in the United States, 1910-56.

Figure 2. Poliomyelitis incidence in 1956 compared with the years 1946 through 1955.

NOTE: Data provided by National Office of Vital Statistics, Public Health Service.

cases showed that in all instances these lots had been used during the summer and in areas experiencing high or epidemic incidence of the disease and that these cases did not exhibit the other epidemiological characteristics of the Cutter cases.

When intervals between inoculation and onset were examined for the 229 paralytic vaccinated cases, it was found that 53 percent of the cases occurring 0-15 days after inoculation fell in the 4- to 11-day period, very close to the 50 percent expected by chance. The corresponding percentage for the Cutter cases was 88.

Analysis of the relationship between sites of inoculation and first paralysis showed the following: Of the 229 paralytic cases, 164 had spinal involvement, and of these 164, the site of

inoculation was known for 150. Among these 150, initial involvement included either the inoculated or the opposite uninoculated extremity, or both, in 31. Of these 31, only the inoculated limb was involved in 21, only the opposite uninoculated limb was involved in 6, and both limbs were involved in 4. This slight excess of correlated cases (21) over uncorrelated cases (6) may indicate the occurrence of a small number of vaccine-related cases. However, the correlated cases were spread among 19 lots of vaccine. Also, analysis of a comparison group of 905 cases that occurred more than 30 days after vaccination showed a similar excess of correlated over uncorrelated cases (13 and 6, respectively). Although the frequency of correlation in the small group of under-30-day cases suggests vaccine-related poliomyelitis, the

similar frequency of correlation for the over-30-day cases precludes any definite conclusion. However, if it is assumed that the excess of 15 correlated under-30-day cases was due to prior inoculation, then the vaccine has influenced the development of considerably less than one paralytic case per million inoculations.

Vaccine Reactions

Vaccine reactions that have been considered possible hazards include encephalitis or other neurological illnesses such as may occur following use of smallpox or other vaccines; allergic reactions to the traces of penicillin and foreign proteins in the vaccine; nephritis or other renal diseases attributable to reaction to residual monkey kidney proteins in the vaccine; and sensitization of Rh negative persons by Rh positive antigen potentially present in the vaccine. To evaluate these hazards, the Poliomyelitis Surveillance Unit has collected reports

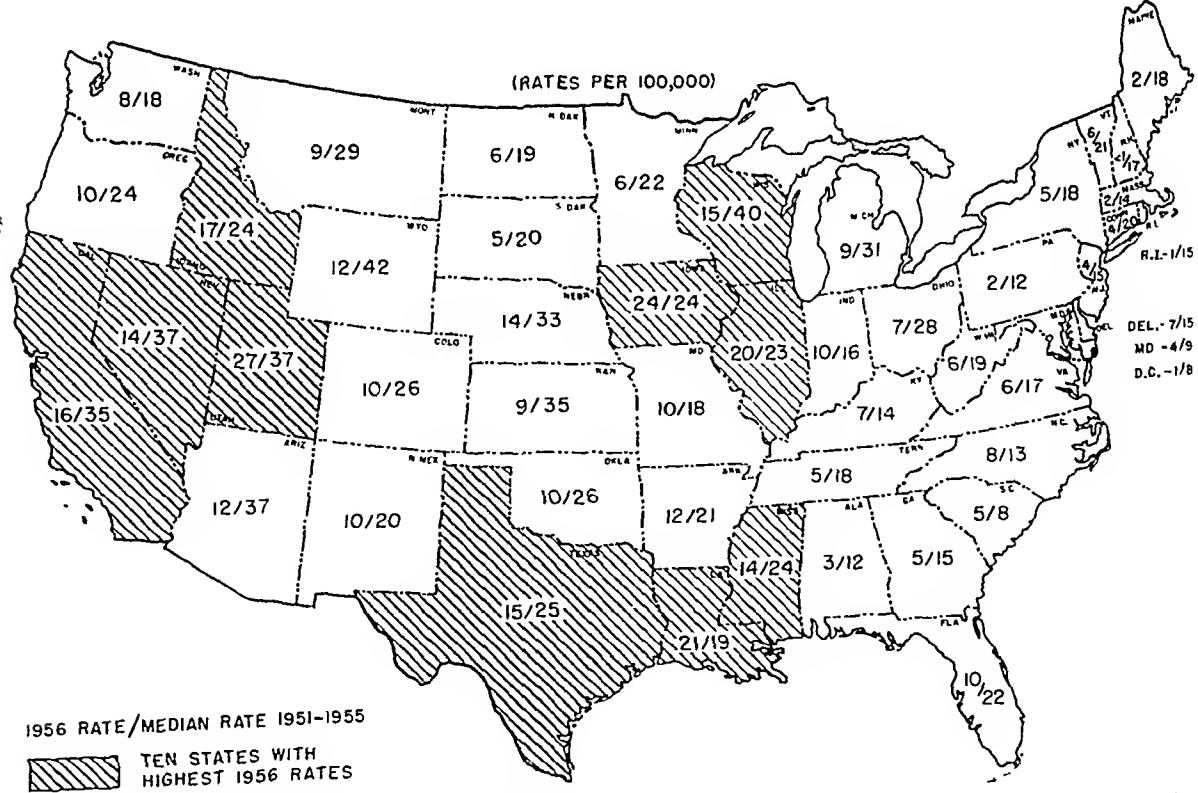

Table 1. Reported poliomyelitis incidence rates for 1956 and median rates for 1951-55, by geographic region

| Region ¹ | Rate for 1956 ² | Median rate for 1951-55 ² |
|---------------------|----------------------------|--------------------------------------|
| United States----- | 9.2 | 23 |
| Northeast----- | 3.5 | 17 |

¹ Provisional data reported to the National Office of Vital Statistics, Public Health Service.

² Includes cases reported with paralytic status unspecified (2,714 for the United States).

³ None of the cases reported so designated.

• Vaccine reactions are rare.

• Neurological illnesses following vaccination include 2 cases of encephalitis, 5 cases of myelitis, 1 sudden death (no definite cause found on autopsy), and a small number of minor self-limited illnesses such as meningismus, febrile convulsions, and labyrinthitis. It appears unlikely that these illnesses are related to prior vaccination, but further information must be collected, particularly on cases of encephalitis and myelitis, before any final evaluation can be reached.

• Local or generalized mild allergic reactions (such as urticaria) may occur in rare instances following vaccination. Two reports have been received of more severe dermatological illnesses following vaccination, but their relationship to prior inoculation appears questionable.

Table 3. Percentage distribution of paralytic and nonparalytic poliomyelitis cases, by age group, 1952, 1955, 1956¹

| Age group (years) | Percent distribution | | | | | |
|--------------------|----------------------|------------|------------|--------------|------------|------------|

| Total | 100 | 100 | 100 | 100 | 100 | 100 |

¹ Based on provisional data, including 21,971 cases from 22 States in 1952, 18,378 cases from 34 States in 1955, and 10,286 cases from 45 States in 1956. Cases in which paralytic status was not stated are excluded.

- There have been no reports of nephritis or other renal disease following vaccination.
- There have been no reports of hematological illnesses in which vaccine was considered to play a role.

Vaccine Effectiveness

Evaluation of vaccine effectiveness includes an analysis of the age distribution of cases by vaccination and paralytic status, a special study of the frequency of paralysis in hospitalized patients according to number of vaccine doses, special studies in three States comparing attack rates among vaccinated and unvaccinated children, and an analysis of reports of cases among persons who had received three doses of vaccine.

Age Distribution Analysis

During 1956, 44 States, the District of Columbia, and 3 Territories cooperated with the Poliomyelitis Surveillance Unit in an age distribution study. They reported to the unit the age, paralytic status, and vaccination history of all verified cases of poliomyelitis. These cases represent about three-fourths of all cases reported for the Nation. Data by age and paralytic status for 1955 and 1952, collected from a number of States in a similar study conducted in 1955, were available for comparison. Three separate qualitative measures of vaccine effectiveness are apparent from a preliminary analysis of the 1956 data in relation to the earlier data.

A definite shift was observed in the age distribution of paralytic cases. In comparison with data for 1955 and 1952, 1956 data showed an increase in relative incidence in the under-5-year age group, with a compensatory decrease in the relative incidence in the 5-to-9-year age group (table 3). No significant change was apparent in the age distribution of nonparalytic cases. This shift in age distribution of paralytic cases may be associated with the known fact that the young school age group was more extensively vaccinated than the preschool age group. In particular, children in the first and second grades of school in the spring of 1955, who were largely 8- and 9-year-olds during the past poliomyelitis season, were thoroughly vac-

inated in school clinics sponsored by the National Foundation for Infantile Paralysis. The reduction in paralytic incidence in this group is apparent in figure 4, which shows age-specific attack rates by single years of age. The paralytic age curve peaks sharply at age 1 and decreases rapidly through age 6. Except for the trough at ages 8 and 9, the age-specific rates remain relatively constant from ages 7 to 30, decreasing gradually thereafter.

Although the overall frequency of paralysis by age groups was similar to that reported in 1955 (table 4), the frequency of paralysis among reported cases in the under-20-year age group was markedly lower among vaccinated cases, 34 percent, than among unvaccinated cases, 60 percent (table 5). This difference supports the conclusion that vaccination prevented some paralysis.

Among the paralytic cases reported during the midsummer season in the under-20-year age group, 21 percent were vaccinated (table 6). This figure may be compared with estimates of the proportion of the population under 20 that had received one or more doses by that time. A conservative figure is 50 percent. The difference points to a vaccine effectiveness of the order of 75 percent against paralytic poliomyelitis. (Seventy-nine percent of the paralytic cases occurring in the unvaccinated population and 21 percent occurring in the same number of vaccinated persons indicate a reduction in the vaccinated rate compared with the unvac-

Figure 4. Age distribution of poliomyelitis in the United States, 1956.

| Age group (years) | Percent paralytic | | |
|-------------------|-------------------|------|------|
| | 1952 | 1955 | 1956 |
| 0-4----- | 69 | 65 | 69 |
| 5-9----- | 56 | 44 | 40 |
| 10-14----- | 57 | 44 | 43 |
| 15 and over----- | 64 | 53 | 50 |
| All ages----- | 62 | 52 | 52 |

¹ Based on provisional data, including 21,971 cases from 22 States in 1952, 18,378 cases from 34 States in 1955, and 10,286 cases from 45 States in 1956. Cases in which paralytic status was not specified are excluded.

inated rate proportional to the reduction from 79 to 21. This reduction is $(79-21) \div 79 = 73$ percent.) A similar computation may be made for the 5-to-9-year age group. It is estimated that at least two-thirds of this age group had been vaccinated, while one-third of the paralytic cases in the age group were vaccinated (fig. 5 and table 6). This difference again leads to a crude estimate of 75 percent effectiveness against paralytic poliomyelitis. (Two-thirds of the paralytic cases occurring in the unvaccinated population and one-third in twice as many vaccinated persons indicate a reduction in the vaccinated rate compared with the unvaccinated rate proportional to the reduction from $\frac{2}{3}$ to $\frac{1}{3} \div 2$. This reduction is $(\frac{2}{3} - \frac{1}{3}) \div \frac{2}{3} = 75$ percent.)

The National Foundation for Infantile Paralysis conducted a study of hospitalized poliomyelitis patients during the height of the 1956 poliomyelitis season. Reports were received on 3,198 patients with acute cases in 408 hospitals in 48 States. When these patients were grouped according to number of vaccine doses received prior to onset, the frequency of paralysis declined progressively from 59 percent among unvaccinated patients to 23 percent among those who had received three doses (fig. 6). Thus, this study provides additional evidence of the effectiveness of the vaccine in 1956.

Special Studies in Three States

During the past year California, Florida, and Minnesota were able to follow the distribution of vaccine in sufficient detail to obtain reasonable estimates of vaccinated populations by age groups. Current State estimates of the total population in the age groups studied were used. After estimation of the size of the vaccinated group, the size of the unvaccinated group was obtained by subtraction. Attempts at direct measurement of vaccine effectiveness during 1956 in preventing paralytic poliomyelitis were thus possible in these States.

Several factors introduce sources of potential bias in these analyses. Case reports were received through morbidity reporting systems of widely varying accuracy. Total population

¹ Based on preliminary and incomplete data from 45 States. A total of 1,107 cases, representing 10 percent of the total reported cases in these States, are excluded because one or more of the following were reported as

unknown: paralytic status, vaccination history, month of onset, or age.

² Cases with one or more inoculations prior to onset are classified as vaccinated.

figures and vaccine usage figures (particularly for commercial supplies of vaccine) were necessarily estimates. Variations in geographic and age-specific vaccination rates and attack rates could not be completely accounted for. Risk of exposure was assumed to be equal in the two populations and constant throughout the study period. Although attempts have been made to minimize the effect of these sources of error, interpretations of the results must necessarily be guarded.

Figure 5. Percentage of paralytic and nonparalytic poliomyelitis cases reported as vaccinated and as not vaccinated, 1956.

NOTE: Preliminary and incomplete data from 45 States.

Estimates of effectiveness according to numbers of doses are not reported here. Thus, the estimates represent overall effectiveness of varying composites of 1, 2, and 3 doses of vaccine and should be interpreted accordingly.

Preliminary results of these studies are summarized in table 7. In each State, paralytic attack rates were significantly lower among vaccinated persons than among unvaccinated persons. Each of these independent studies indicates an overall vaccine effectiveness in preventing paralytic poliomyelitis of about 75 percent. These results are in general agreement with results of similar analyses conducted in 1955 (1).

Triple-Vaccinated Cases

In September 1956 a national registry was established in the Poliomyelitis Surveillance Unit for reports of poliomyelitis among individuals who have received three doses of vaccine. Recorded data include clinical, epidemiological, and laboratory information. Residual paralysis is being documented by convalescent muscle gradings or supplemental descriptions from attending physicians. In a few cases followup information has resulted in a revised diagnosis or changed paralytic or vaccination status. Triple-vaccinated cases reported through January 18, 1957, have received the following classifications:

| | Number of cases |
|--|-----------------|
| Nonparalytic..... | 154 |
| Paralytic..... | 34 |
| Confirmed, with residual paralysis..... | 19 |
| Under investigation..... | 9 |
| Revoked (not paralytic or not vaccinated)..... | 6 |
| Total cases..... | 188 |

More stringent criteria have been applied in establishing these triple-vaccinated cases as par-

¹ Based on preliminary and incomplete data from 45 States. A total of 1,107 cases, representing 10 percent of the total reported cases in these States, are excluded because one or more of the following were reported as

unknown: paralytic status, vaccination history, month of onset, or age.

² Cases with one or more inoculations prior to onset are classified as vaccinated.

alytic poliomyelitis than are used in the routine reporting of the disease. For this reason it is not possible to compare directly these triple-vaccinated cases with other groups of paralytic cases, vaccinated or unvaccinated.

Laboratory specimens have been collected on 16 of the 19 confirmed paralytic cases. Poliovirus was isolated from 7, other virus from 2, and no virus from 3. Final laboratory results have not yet been submitted on the four remaining cases. Thus, to date, seven triple-vaccinated paralytic cases have received laboratory confirmation.

Three deaths from poliomyelitis have been reported in triple-vaccinated persons. One case was established as bulbar poliomyelitis, but a recheck of vaccination records revealed that the child had never been vaccinated. A second case was clinically consistent with poliomyelitis, but pathological review revealed instead the anatomic findings of acute disseminated encephalo-

myelitis. The one remaining fatal case occurred in a 5-year-old boy who died the day after onset of fever and within 30 minutes of hospitalization. Findings of an autopsy performed without examination of the brain or spinal cord were reported as compatible with poliomyelitis. This is the only fatal case now being carried in the registry.

Vaccine Under Epidemic Conditions

There has been particular interest in evaluation of the effectiveness and possible dangers of administering poliomyelitis vaccine during epidemics. In particular, based on previous studies with diphtheria and pertussis antigens, it had been feared that the vaccine might "provoke" the development of subsequent paralysis in persons infected at the time of, or shortly after, vaccination. The first study of this problem was conducted during a small outbreak of poliomyelitis among U. S. Navy personnel and

figures and vaccine usage figures (particularly for commercial supplies of vaccine) were necessarily estimates. Variations in geographic and age-specific vaccination rates and attack rates could not be completely accounted for. Risk of exposure was assumed to be equal in the two populations and constant throughout the study period. Although attempts have been made to minimize the effect of these sources of error, interpretations of the results must necessarily be guarded.

A more complete presentation of findings in Chicago during 1956 will be published under the direction of Dr. Herman N. Bundesen, president, Chicago Board of Health.

Vaccine Distribution

During 1955 and 1956 a total of 98.2 million doses of poliomyelitis vaccine were distributed for domestic use, including 27.7 million doses from April through December 1955 and 70.5 million doses in 1956. An additional 6.5 million doses were exported during recent months of 1956. Through the end of 1956, a cumulative total of 130.6 million doses of vaccine (net cubic centimeters of bottled vaccine) had been released after clearance by the National Institutes of Health, Public Health Service, leaving a balance of 25.9 million doses on hand at the close of the year.

Distribution of vaccine by calendar quarters is presented in figure 7. Quarterly shipments of vaccine reached a peak in the second quarter of 1956, when 27.8 million doses were distrib-

uted. Shipments declined progressively during the last two quarters of 1956, lagging considerably behind vaccine releases. This progressive accumulation of vaccine available for use is also shown in figure 7.

Of the 98.2 million doses distributed domestically, 13.7 million were purchased by the National Foundation for Infantile Paralysis, primarily for vaccination of first- and second-grade school children in 1955, 53.5 million were distributed through public agencies, and 31.0 million were distributed through normal drug channels. Specific usage by age group and by first, second, or third inoculation for only a part of this vaccine is known.

There are between 60 and 65 million persons under 20 years of age in the United States and Territories. Just over half enough vaccine has now been distributed to complete three inoculations for each individual in this group. More than 100 million doses in addition would be required to complete vaccination of the population aged 20 to 40.

dependents in Hawaii in late 1955 (2). This analysis revealed no evidence of a "provoking" effect.

In 1956 the largest concentration of poliomyelitis occurred in Chicago, where more than 1,100 cases were reported. This outbreak presented an unusual opportunity for the study of mass vaccination under epidemic conditions. In collaboration with the Chicago Board of Health, the Cook County Health Department, the Illinois Department of Public Health, the division of services for crippled children of the University of Illinois, and the National Foundation for Infantile Paralysis, the Public Health Service undertook an epidemiological, clinical, and

⁴ Difference between unvaccinated and vaccinated rates, divided by unvaccinated rate. Vaccine effectiveness thus expresses the percent reduction in the vaccinated attack rate as compared with the unvaccinated rate. Presumably, this reduction is due largely to the vaccine.

⁵ Calculated at the 95 percent confidence level according to the method used by Francis and associates (reference 3, appendix, p. 62).

laboratory study of poliomyelitis cases occurring in Chicago and suburban Cook County.

Preliminary analysis of epidemiological data showed patterns differing markedly from previous years, particularly the last previous epidemic year of 1952. In 1952 cases were scattered quite evenly throughout the city. In 1956 early cases were also scattered widely, indicating a general dissemination of the virus. However, as the outbreak progressed, high rates developed only in those areas of the city characterized by a particularly dense population, a low socioeconomic status, and a high proportion of nonwhites. In 1952 cases among nonwhites constituted 14 percent of the total cases as compared with 61 percent in 1956. In 1956 there was a shift in the age distribution of cases toward the preschool age group. This shift was particularly marked for the cases in the white population.

Preliminary analysis of clinical and laboratory data has revealed no unusual findings. About 60 percent of the cases were reported as paralytic. Stool specimens obtained from a large number of cases and examined by the laboratories of the Illinois Department of Public Health yielded predominantly type 1 poliovirus.

In late July 1956, during a period of rapidly rising incidence, the Chicago Board of Health initiated a large-scale mass vaccination program. Through the cooperative efforts of medical and other organizations in the city, more than 1.5 million doses were administered in less than 2 months. However, this program began too late to demonstrate any dramatic effect upon the epidemic curve.

In an attempt to delineate any possible "provoking" effect following this large number of inoculations, a preliminary analysis of about 400 vaccinated cases (including more than 300 cases occurring within 30 days of inoculation) was made. This analysis revealed no evidence that prior inoculation influenced the localization of subsequent paralysis. Among paralytic cases, there were 11 with initial involvement of the inoculated limb, 11 with initial involvement of the opposite uninoculated limb, and 13 with involvement of both the inoculated limb and the opposite uninoculated limb.

Poliomyelitis Vaccination Program in Richland, Wash.

By DAVID B. ROWLETT, M.D., and CAESAR BRANCHINI, M.A.

IN RICHLAND, WASH., a community of 26,000 population, statistical evaluation of the status of poliomyelitis vaccination, followed by the education of private physicians and co-operation between these physicians and the Richland Health Department, increased the percentage of vaccinated children in the survey from about 56 percent to 80 percent. The term "vaccinated" as used in this paper refers to those children who have received at least one shot of Salk vaccine. Although we realize that one shot confers neither complete nor lasting protection, we assume that children who have received one shot will complete the series.

In the event that other communities attempt to determine their poliomyelitis vaccination status, the statistics obtained in this study may serve as a base point for comparison with their findings.

Setting the Stage

A balance in supply of and demand for the Salk vaccine was not achieved in Richland until the early spring of 1956. During 1955 the vaccine was available in adequate supply but there was no demand for it. Early in 1956, due to the change in public opinion regarding the safety and effectiveness of the vaccine, the demand was rapidly accelerated and the supply fell short. Private physicians developed waiting lists of hundreds of patients who were patiently awaiting the arrival of more vaccine.

Dr. Rowlett is public health officer and industrial physician, and Mr. Branchini is a specialist in health education, Hanford Atomic Products Operation, General Electric Company, Richland, Wash.

The situation was eased about the middle of March. Between March and October 1956 the Richland Health Department, the National Foundation for Infantile Paralysis, and private physicians recommended the Salk vaccine and gave widespread but low-pressure publicity to its safety and effectiveness. The usual methods of dissemination of information were used. Leaflets were distributed through the schools and through the Hanford Atomic Products Operation plant, the chief industry in the Richland area. Newspaper stories were released recommending vaccination and reporting the amount of vaccine available. Radio and television announcements supplemented the information program.

Between March and October 1956 vaccinations were given by private physicians in their offices. When Government-purchased vaccine became available, it, too, was distributed to private physicians for office use. During this period, no clinics were held and no vaccinations were administered by the health department.

Continuous checks showed that the demand for the vaccine exceeded the supply. However, this situation began to reverse itself during September.

Health Department Study

It was at this point that the Public Health Operation of the General Electric Company's Hanford plant (local nomenclature for the Richland Health Department), which operates all Richland municipal facilities for the Atomic Energy Commission, undertook a study to de-

Discussion and Summary

The experience in the United States during 1956 shows that poliomyelitis vaccine has been safe and effective. Several hundred cases of poliomyelitis occurred shortly after inoculation, but this many vaccine-associated cases could easily be coincidental in view of the more than 70 million doses of vaccine that were administered. The vaccine-associated cases had all the characteristics of naturally occurring poliomyelitis. There was slight, if any, evidence of untoward reactions from the vaccine. While the concepts of absolute vaccine safety or total absence of a provoking effect of inoculation are not scientifically tenable, the epidemiological observations during 1956 indicated that any such hypothetical effects occurred at a frequency of less than one per million inoculations.

During 1956 the effectiveness of the vaccine could not be evaluated in well-controlled field studies, such as Francis conducted in 1954 (3), or in large-scale comparison-group studies such as were made in 1955 (1). It was necessary to depend largely upon qualitative studies and upon orderly epidemiological inferences based on careful observation and analysis. A number of independent studies consistently point to a level of effectiveness in preventing paralytic cases of 75 percent, with a large proportion of the vaccinated population having received less than the recommended course of three doses. The effectiveness of three doses, properly spaced, has not yet been fully evaluated, but the occurrence of several well-confirmed triple-vaccinated paralytic cases shows it to be less than 100 percent.

Considerable evidence has accumulated to show that the present vaccine is less effective in preventing nonparalytic cases and in controlling the spread of inapparent infection. Two published studies (4, 5), as well as unpublished work of Lipson, Carver, and Robbins and of Davis and Melnick, have shown that

vaccinated children in household contact with poliomyelitis cases can readily become infected, although, again, the effect of three doses has not yet been fully evaluated. Thus the primary effect of vaccine appears to be the prevention of invasion of the central nervous system and thereby the prevention of paralysis. This limitation on the effectiveness of the vaccine may be associated with the evidence that poliovirus did spread rather extensively in various populations during 1956, not only in Chicago, but in Louisiana, Utah, Idaho, California, and elsewhere. In spite of relatively widespread, but incomplete, vaccination, these populations experienced high incidence of disease, particularly among preschool children in all socioeconomic groups.

The immediate public health implication of the experience in 1956 is that substantially higher levels of immunity must be achieved among all elements of the population.

cination series, was 44 percent. This proportion, however, varied considerably, from a low of 29.1 percent for third grade children to a high of 76.2 percent for senior high school children. The percentage of unvaccinated children in each school grade is shown in figure 2.

Vaccination Program

When the information on the vaccination status of the school children of Richland was tallied, it was decided that, although the level of protection achieved against poliomyelitis was high, it would be desirable to increase this level considerably for two reasons: (a) those who by this time had not taken advantage of the opportunity to obtain this protection would not do so voluntarily or, if they did, they would do so only in small numbers; and (b) the level of protection in the junior and senior high schools was so inadequate that considerable emphasis needed to be placed on these groups.

A vaccination program was proposed by the health officer of Richland. The plan was discussed with and approved by the local physicians, and the program was undertaken in the schools. Vaccinations were scheduled to be given during the last 2 weeks in October and the last 2 weeks in November 1956. Three groups of children were to receive shots of Salk vaccine:

Figure 1. Percentage of children in Richland, Wash., who received the designated number of shots of Salk vaccine in 1956, by school group, prior to the vaccination program.

Figure 2. Percentage of children in Richland, Wash., who did not receive Salk vaccine in 1956, by school group, prior to the vaccination program.

1. Children who had received no previous shots would be given one shot in October and a second shot in November.

2. Children who had received only one shot, if it was given from 2 weeks to 6 months before either vaccination period, would be given their second shot during the October or November immunization schedule.

3. Children who had received two shots 7 months or more before October 1956 would be given their third shot during either of the vaccination periods.

In the secondary schools public health nurses discussed the safety and effectiveness of the vaccine in meetings with the students. The National Foundation for Infantile Paralysis film "Unconditional Surrender" was shown to all students, and a 15-minute television program was devoted to a discussion of the need for immunization among secondary school students.

The first half of the poliomyelitis vaccination program in the Richland schools was completed in November. Of the total population of school age and under, 80 percent have received at least one shot in the Salk vaccine series. The level of vaccinated children in the high school is 61 percent. Of the junior high school group, 80 percent have received at least one shot of vaccine; of the elementary school pupils, 87 percent.

termine the vaccination status of the children of the community. Children of school age and under comprise 42.2 percent of the total population of Richland.

The object of the study was to provide information on the current level of protection against poliomyelitis to help the health department decide whether a change in the vaccination program was needed. The study would also provide basic information from which to determine the effectiveness of the vaccination program and, later, the effectiveness of the vaccinations.

Study Methods

Two groups of children were studied and each group had to be treated differently. The first group was made up of school children. These children were easily reached through our regular school health program, since the public health nurses provide school health services in the community. The second group was made up of preschool children, and information on this group was more difficult to obtain.

A form which explained the advisability of vaccination against poliomyelitis and pointed out the safety and effectiveness of the Salk vaccine was prepared and was given each school child to take home. On the form parents were asked to indicate the number and approximate dates of shots of Salk vaccine received by each child and were offered the opportunity to continue the vaccination program with their private physicians. They were also requested to sign an attached slip if they were interested in administration of the vaccine by the health department.

At each school the public health nurse distributed the forms to the teachers. As is done routinely in other immunization programs, the teachers distributed the forms to the children and collected them when they were returned. The public health nurse collected the completed forms and delivered them to the health department, where the information was consolidated.

A sampling technique was used to obtain details of the vaccination histories of preschool children. In order to reduce the size of the sample, birth certificates of children born during 1952-56 were used to select the sample. To

Poliomyelitis vaccination status of children in Richland, Wash., as of October 1956

| Grade | Number shots of Salk vaccine received | | | | Total children in program |
|-------------------------|---------------------------------------|-----|-------|-----|---------------------------|
| | 0 | 1 | 2 | 3 | |

assure anonymity, only the child's address was used, and a letter was mailed to the resident at that address. The letter explained the program and the fact that in order to plan a poliomyelitis vaccination program, information was needed on the vaccination history of all children in the community. Respondents were asked to indicate on an enclosed card the ages of preschool children in the household and the approximate dates when they had received Salk vaccine shots.

The information on the sample of preschool children was combined with the information on school children.

Findings

Information was obtained on 9,655 of the 10,977 children in the preschool and school age groups. The immunization status of the children in the study is shown in the table. Figure 1 shows the percentage of children in each grade who received the designated numbers of shots of Salk vaccine.

Our chief objective was to determine which children had not been vaccinated, in order that we might take steps to achieve a higher degree of protection against poliomyelitis if the collected data indicated a need for greater protection.

The proportion of children who had not been vaccinated, that is, who had not received any shots of Salk vaccine in the poliomyelitis vac-

use of general hospitals

MAURICE E. ODOROFF, M.A.

LESLIE MORGAN ABBE, B.S.

Drawn from data compiled in a national household survey, this report gives provisional findings on current levels of general hospital use in relation to personal and geographic characteristics.

PLANNING for general hospitals has included a continuing search for valid standards of need. In 1947 uniform standards for the number of beds needed came into general use with the development of statewide hospital plans under the Hospital Survey and Construction (Hill-Burton) Act. These standards reflected the consensus of judgment of the period. They were largely lacking a base of actual experience in the needs of a population whose characteristics were known (1). During the subsequent decade the Nation's general hospital plant has increased by one-fourth, or more than 150,000 beds. At the same time changing techniques in the care and prevention of disease and illness have modified requirements for the physical facilities to insure adequate care. It is now essential to reassess these requirements.

Mr. Odoroff is chief, and Mr. Abbe is assistant chief, Program Evaluation and Reports Branch, Division of Hospital and Medical Facilities, Public Health Service.

As a first step in defining more precisely standards of need for general hospitals, the Public Health Service, through its Division of Hospital and Medical Facilities, has contracted for a survey of the present level of use of general hospitals. The data on use have been matched with data on personal characteristics and geographic and economic factors. Such a study permits identifying the circumstances which accompany varying levels of use and points the way to more intensive studies of real need. It achieves a link with the population served that cannot be had through studies of hospital records alone, since these records cover only those who choose to use the hospital.

Description of Study

The study of general hospital use is based on a sample household survey on a national scale. It was conducted by the Bureau of the Census through supplemental questions asked in its regular monthly current population survey.

These percentages are based on the assumption that all of those who have not responded to the questionnaire have not received any shots.

Summary

A study to determine the poliomyelitis vaccination status of all children of school age and

under was carried out in 1956 in Richland, Wash., a community of 26,000 population. Through the close cooperation of private physicians and the health department, 80 percent of the children in the age groups studied received Salk vaccine.

Cost Study of Poliomyelitis Vaccine Injections

A time and cost study in the Tri-County, Colorado. District Health Department found that the average cost of administering poliomyelitis vaccine in public poliomyelitis vaccination clinics of that department in 1956 was 26.5 cents for each injection, not including vaccine cost. The study was carried out by the staff of the Region 8 office of the Public Health Service in Denver.

The Tri-County District Health Department, directed by William S. Haynes, M.D., M.P.H., has jurisdiction over the three counties surrounding Denver—Adams, Arapahoe, and Jefferson. The vaccination clinics were held principally in the department's branch health centers in each county.

There were 112 clinic sessions in which 50,585 injections were given. The total cost of the clinics in 1956 was \$13,425.23, consisting of \$5,856.54 direct costs, \$4,037.19 nursing costs, and \$3,531.50 health department general overhead costs.

Direct costs cover expenditures for specialized poliomyelitis vaccine clinic supplies and equipment, fees to physicians (on an hourly rate) for administration of the vaccine, salaries of part-time clinic nurses, and salary of a clerk working exclusively with the poliomyelitis vaccination program. The vaccine, which was furnished by the Colorado Department of Public Health, was purchased with Federal grant-in-aid funds available to Colorado under the Poliomyelitis Vaccination Assistance Act of 1955.

The nursing cost item includes the cost of nursing services furnished by the visiting nurse services of the Tri-County Department to the public clinic program. It covers a part of the health department overhead costs allocated to the nursing service and the salary value of productive work by students in the clinics.

The pro rata share of health department overhead costs covers an allocation of these costs on a dollar pro rata basis computed on direct costs against overhead costs, excluding those allocated to nursing.

The overhead costs include the salary and travel costs of the health officer, clerks, and administrative staff; capital outlay; janitor and office supplies; medical and clinical supplies; building maintenance; telephone; postage; printing; estimated rental value of space used in publicly owned buildings; per diem payments to board of health members; and attorney fees.

"Housewife" volunteers devoted about 1,000 hours of service to the program. This service, if valued at \$1 per hour, would raise the cost of each injection by 2 cents.

Drawn from data compiled in a national household survey, this report gives provisional findings on current levels of general hospital use in relation to personal and geographic characteristics.

PLANNING for general hospitals has included a continuing search for valid standards of need. In 1947 uniform standards for the number of beds needed came into general use with the development of statewide hospital plans under the Hospital Survey and Construction (Hill-Burton) Act. These standards reflected the consensus of judgment of the period. They were largely lacking a base of actual experience in the needs of a population whose characteristics were known (1). During the subsequent decade the Nation's general hospital plant has increased by one-fourth, or more than 150,000 beds. At the same time changing techniques in the care and prevention of disease and illness have modified requirements for the physical facilities to insure adequate care. It is now essential to reassess these requirements.

Mr. Odoroff is chief, and Mr. Abbe is assistant chief, Program Evaluation and Reports Branch, Division of Hospital and Medical Facilities, Public Health Service.

As a first step in defining more precisely standards of need for general hospitals, the Public Health Service, through its Division of Hospital and Medical Facilities, has contracted for a survey of the present level of use of general hospitals. The data on use have been matched with data on personal characteristics and geographic and economic factors. Such a study permits identifying the circumstances which accompany varying levels of use and points the way to more intensive studies of real need. It achieves a link with the population served that cannot be had through studies of hospital records alone, since these records cover only those who choose to use the hospital.

Description of Study

The study of general hospital use is based on a sample household survey on a national scale. It was conducted by the Bureau of the Census through supplemental questions asked in its regular monthly current population survey.

This survey provides official Government statistics on total employment and unemployment, as well as periodic data on many other social and economic characteristics of the population (2, 3). The sample used in the survey of hospital use was drawn from the civilian, noninstitutional population living within the continental United States. It did not include members of the armed services or inmates of penal and mental institutions or of homes for the aged, infirm, and needy. It includes about 27,000 households (three-fourths of the regular sample size of the current population survey), consisting of about 90,000 persons of all ages. The sample was spread over 330 areas comprising 638 counties and independent cities, with coverage in each of the 48 States and the District of Columbia. The survey was made in September 1956 after a pretest in Philadelphia in June 1956, which included about 650 households and 2,100 persons.

For each family a history was obtained of hospitalization and outpatient care received by each of its members during the previous 12-month period. The questions asked sought to learn how frequently, how long, for what conditions, and in what hospitals or related facilities such care was obtained. Personal characteristics, such as residence address, sex and race, age, veteran status, and occupation, were identified through the standard inquiries of the regular monthly current population survey.

In addition, economic data were obtained for each household, showing income level, status with respect to hospital insurance coverage, and methods of payment for hospital care received. Particular attention was given to determining the place of care with respect to the type of place of residence (metropolitan, urban, or rural) of the patient. Throughout the study the terminology used follows standard definitions of the Bureau of the Census (4).

Certain limitations of the data must be noted. Institutional population is excluded for practical reasons arising from the method of survey. Also, any approach to reporting by household survey for a 12-month prior period of time fails to include a record of persons who used hospital care during the past year, but who died, emi-

grated, or entered the armed services before the survey date.

The figures reported are estimates based on a sample. Accordingly, they may differ somewhat from the figures that would have been obtained if a complete census had been taken, using the same questions, instructions, and enumerators. Sampling variability may be relatively large when the estimates and differences between estimates are small. The degree of variability will be calculated for selected items according to standard statistical procedures. As in any survey work, the results are subject to errors of response and reporting.

Scope of the Report

Because of the general interest indicated by a number of national groups and others, this report is published as an interim account of results before all data have been tabulated or analyzed. The data appearing are selected highlights. They relate only to levels of hospital use matched against personal characteristics and geographic circumstances of residence and place of care. They will need further study and analysis in relation to other data of the survey. Additional interim reports will cover (a) limited data on outpatient visits and the accompanying circumstances, (b) income of all families and individuals in the

sample in relation to their levels of general hospital use, and (c) the proportion of hospital insurance coverage reported for all persons in the sample, matched with various personal, geographic, and economic circumstances. It is planned to publish a comprehensive report of the study as a monograph.

Two basic measures of the level of hospital use in varying circumstances have been compiled from the survey data. These are annual admissions per 1,000 population and average stay in days per admission. In this report, these two measures describe the relation between hospital use and a group of personal characteristics that may be considered demographic factors. They also describe the relation between use and a group of factors pertaining to the nature of the geographic and

Table 3. General hospital use among males 14 years old and over, by veteran status and type of hospital

| Nonveterans..... | 82 | 11.0 |

social setting of the place of residence and the place of care. For the purposes of this study, these factors are classed as ecologic factors.

Demographic Factors

Sex and race result in marked differences in general hospital use for the population surveyed (table 1).

Annual admissions per 1,000 population total 101 for all persons. For females the rate (including maternity cases) is about one-fourth higher; for males, about one-fourth lower. The rates for the nonwhite population of both sexes are substantially lower than those for white persons.

The average stay for all persons is 8.1 days, with differentials by sex about as great as for admissions, but in the opposite direction.

Table 4. General hospital use among persons 14 years old and over, by employment status and industry

| Employment status and industry | Annual admissions per 1,000 population | Average stay per admission, in days |

¹ Includes a central city of at least 50,000 population with contiguous counties socially and economically integrated therewith, as defined by the Bureau of the Census (4).

² Insufficient number of cases to justify entry.

NOTE: Discrepancies in totals result from rounding.

Women are admitted more frequently than men, but stay a shorter time.

Age affects substantially the pattern of admissions and average stay in general hospitals (table 2).

For children under 14 years of age the admission rate of 54 per 1,000 population is only slightly more than one-half the rate for all ages. It rises steadily, by 10-year age groups, to a rate of 162 for ages 25-34 (the principal child-bearing age group). The rate then declines to 93 for the age group 45-54 and rises thereafter. For the group aged 65 and over, the rate for the sample study is 125 per 1,000 population.

Average hospital stay for the childhood group is reported at 5.2 days, rising gradually to a maximum of 14.0 days for persons 65 years and older.

Veteran status has little effect on admissions and average stay, according to the record for all males 14 years of age and older (table 3).

Veterans of World War II have an admis-

sion rate of 80 per 1,000 population and an average stay of about 12 days, in comparison with a rate for other veterans of 90 admissions and a stay of about 14 days.

Both groups of veterans are receiving care principally in non-Federal hospitals. The typical stay for veterans in Federal hospitals is from 4 to 5 weeks; it is about 10 days in non-Federal hospitals.

Employment status and industry produce substantial differences in admissions, with varying effect on average stay for specific industries and employment groups (table 4).

For all persons 14 years of age and over, annual admissions are at a rate of 120 per 1,000 population. For those in the labor force, the admission rate is 82. The rate drops to 57 for those in agriculture and rises to 97 for the unemployed group and 138 for persons in mining (including forestry and fisheries). For persons not in the labor force (homemakers, students, the disabled, and others), the combined admission rate is 174. Persons classified as unable to work have an admission rate of 239, with an average stay of 26 days.

Table 5. General hospital use, by region and type of residence

Ecologic Factors

Geographic region and type of residence have a considerable effect on admissions and average stay (table 5).

Admissions of persons who live on farms are consistently lower than other admissions. Nationally, the admission rate for farm people is one-sixth less than for the total population. This differential holds for 3 of the 4 broad regions of the country. In each region, the highest level of admissions is for rural nonfarm residents.

Type of residence and place of care, as they reflect accessibility, materially affect levels of hospital use (table 6). To assist in interpreting this complex relation, a third measure has been introduced. Not only does the study identify the place of residence of the patient according to whether it is metropolitan, urban, or rural and compare levels of use for a related array of places of care, but it also identifies the median distance traveled for care from each type of residence to each type of place of care.

Particular effort has been made to discover

the total hospital admissions for this residence group. For rural parts of standard metropolitan areas, the admission rate to the central city is 59 for nonfarm residents and 51 for farm residents.

- Residents of urban nonmetropolitan communities have about 18 percent of their total admissions in a metropolitan area. A substantial proportion of admissions for persons living in smaller urban places (under 10,000 population) is in hospitals of larger communities.

- Residents of rural areas (that is, areas where all places are under 2,500 population) report that only 18 percent of their admissions are in hospitals located in rural areas; another 30 percent are in places under 10,000 population.

- The average stay of central city residents in metropolitan areas is greater than the stay of people who come from elsewhere in the area.

- Persons living outside of metropolitan areas report an average stay considerably below that of people who live in metropolitan areas, except when they go to a metropolitan area for care. Such stay for nonmetropolitan residents averages about 11 days in metropolitan hospitals, as compared with 6 days in hospitals nearer home.

- Farm residents cared for in rural hospitals report an average stay of only about 4 days.

- The median distance traveled by each group does not vary greatly from the national average of 7.4 miles, except for persons receiving care in a metropolitan area which is not their place of residence. Such travel amounts to 40 to 50 miles or more.

Reasons for admission in relation to place of care show relatively less diversity in level of use than do places of residence in relation to place of care (table 7).

Surgery accounts for 25 percent of all admissions, and obstetrics for 22 percent.

Average stay for surgery is 10.6 days and for accidents 12.1 days, as compared with about 5 days for obstetric and pediatric services and an average for all reasons of 8.1 days.

Summary

The Public Health Service is investigating the level of use of general hospitals by a known population, for which selected demographic, ecologic, and economic data are collected. For this purpose, the resources of the Bureau of the Census have been employed in connection with household interviews of its current population survey. The sample used comprises about 27,000 families, including about 90,000 persons of all ages, which is three-fourths of the current population survey sample. The study is intended as a first step in defining standards of need for general hospital beds by identifying the circumstances which accompany varying levels of use.

This interim report records provisional findings on levels of general hospital use in relation to (a) selected factors of personal characteristics of the population surveyed and (b) geographic factors pertaining to location and urban-rural residence of the patients cared for. It also reports on use according to the accessibility of the place of care, as related to the place of residence of the patient, and according to the reason for admission. Special significance attaches to the data describing the level of use provided within the central city of a metropolitan area for patients coming from its urban and rural fringe.

the present pattern of use in metropolitan areas, with respect to the large population groups now found in the fringe areas outside the central city. This is a secondary problem in broad planning for general hospital needs on which very little factual evidence has been available. The urban fringe includes both urban places and unincorporated urban areas.

This survey shows the following principal facts about the relation between place of residence and place of care in affecting levels of use:

- The total admission rate by residence varies from 81 for persons living on farms not in metropolitan areas to 117 for persons living in urban places below 50,000 population.

- The residents of metropolitan areas report an admission rate of 97. Persons living in rural nonfarm residences in metropolitan areas report a rate higher than the metropolitan area average, namely, 107. Residents of the urban fringe in metropolitan areas report an admission rate to the central city of only 46 per 1,000 population, or less than one-half of

Expenses and Income Sources of Dental Students

By SHAILER PETERSON, Ph.D., and WALTER J. PELTON, D.D.S., M.S.P.H.

THE NUMBER of dentists in active practice in the United States rose by almost 5,000 between 1930 and 1955. Despite this numerical gain, the supply of dentists in proportion to population continuously declined. In 1930, there was 1 dentist for every 1,728 persons in the Nation; by 1955, there was 1 dentist to 2,168 persons. A continuation of this adverse trend through the next 20 years will result in the most unfavorable dental manpower supply this country has had since the beginning of the century.

The failure of the dental manpower supply to keep up with population growth has occurred during a period in which dental schools have been training the largest numbers of students in their history. In the 10-year period between 1940 and 1950, enrollments increased by more than 50 percent, to reach an average of almost 12,000 students a year. Enrollments have continued to rise in each year since 1950 but not fast enough to reverse the pattern of shortage. They must be drastically increased to provide enough dentists to care for a larger population and to meet the rise in the level of individual demand for care which is expected to accompany population growth.

Dr. Peterson is secretary of the Council on Dental Education, American Dental Association. An authority on educational research and measurement in dental education, he has served as director of educational measurements of the council and was on the examination staff of the Armed Forces Institute at the University of Chicago. Dr. Pelton is chief of the Division of Dental Resources, Public Health Service, a position he has held since 1951.

The need for raising dental school enrollments poses some serious financial problems for the schools, for the students, and for dentistry as a whole. A study conducted in 1952 (1) revealed that dental schools had large backlogs of equipment and building needs which could not be met because of a lack of sufficient funds. Increases in tuition had done no more than keep pace with postwar inflation. A further rise in tuition would provide some relief for the schools, whose financial difficulties have been aggravated by expanding enrollments. Administrators, however, fear that substantial increases in tuition would inhibit enrollment, and therefore hesitate to place further financial obstacles in the way of qualified students.

That dental education is already a very expensive undertaking for the student is shown in a recently published study of the financial problems of dental students conducted by the Council on Dental Education of the American Dental Association and the Division of Dental Resources of the Public Health Service (2). This investigation, together with the earlier study on the financial status of the schools, provides a foundation for the planning of effective corrective measures which will alleviate the schools' financial problems. It can also serve as a guide in the reappraisal of tuition charges and the establishment of expanded scholarships and other programs of financial aid for students.

Survey Methods

In May 1954, the ADA Council on Dental Education, with the cooperation of dental

New Members of the PHR Board of Editors

Four new members have joined the Board of Editors of *Public Health Reports*. Replacing Dr. Gaylord W. Anderson, Dr. Halbert L. Dunn, Dr. Martha M. Eliot, and Dr. Basil C. MacLean, the appointees will serve on the 13-member board for 3 years ending in 1959.

Mary E. Switzer, who became director of the Federal Office of Vocational Rehabilitation in 1950, was instrumental in developing the expanded vocational rehabilitation law passed unanimously by Congress in 1954. This legislation has united the public and private nonprofit restoration organizations with the States in attacking disability problems. Miss Switzer, long outstanding in her national and international health work, was presented with a distinguished service award by the Department of Health, Education, and Welfare in April 1956. Previously, she had received the National Rehabilitation Association President's Award. Miss Switzer has also been awarded the honorary degree of doctor of humane letters by Gallaudet College, District of Columbia, and Tufts University, Medford, Mass.

Carl C. Dauer, M.D., M.P.H., has been medical adviser to the National Office of Vital Statistics, Public Health Service, since 1950. He received his medical degree from Western University in 1920, and graduated from the Harvard School of Public Health in 1933. Dr. Dauer began his public health career as director of child hygiene with the Marion County Health Department, Salem, Oreg., in 1930. Subsequently, he served as an instructor and assistant professor in preventive medicine at Tulane University and as director of the bureau of preventable diseases, District of Columbia Department of Health. He has held teaching positions at the Catholic University, Georgetown University, and George Washington University Medical Schools. Dr. Dauer, whose contributions to medical literature have been extensive, is a member of the American Epidemiological Society, the Washington Academy of Sciences, the Public Health Service Psittacosis Board, a fellow in the Epidemiology Section of the American Public Health Association, and a diplomate of the American Board of Preventive Medicine.

Mandel E. Cohen, M.D., is on the staff of the Massachusetts General Hospital in Boston and of the department of neurology at the Harvard Medical School. Concurrently, he serves as consulting neuropsychiatrist for the Army, the Public Health Service, and Los Alamos Medical Center. A graduate of Johns Hopkins Medical School, Dr. Cohen received his training largely at the Boston City Hospital and the Massachusetts General Hospital. He was a member of the Department of Medicine and Psychiatry at the Harvard Medical School in 1945, and the following year joined the staff of Tufts Medical School as research professor of psychiatry. His published works include reports on studies of hysteria, neurocirculatory asthenia, epilepsy, manic-depressive disease, heart disease, and vascular disease of the brain.

Franklin H. Top, M.D., is a faculty member of the State University of Iowa, where, since 1952, he has been director of the department of health and head of hygiene and preventive medicine. In the same period, he has also acted as consulting director of the Iowa State Hygienic Laboratories, Iowa City, as well as consultant in infectious diseases at the hospital of the State University of Iowa. He is also director of the Institute of Agricultural Medicine, established in 1955. After graduation from the University of Pennsylvania Medical School in 1928 and the Johns Hopkins School of Hygiene and Public Health in 1935, Dr. Top began his professional career in the Herman Kiefer Hospital in Detroit, becoming hospital director in 1947. During the 2 years spent as professor of epidemiology and pediatrics at the University of Minnesota College of Medical Sciences, Dr. Top edited the *History of American Epidemiology* by C.-E. A. Winslow and associates, 1952. He is also the author of the standard work, *Communicable Diseases*, 1941, 1947, 1955.

Average expenditure of dental students, 1953-54.

and \$4,465, or 38 percent, was charged to school expense. Tuition and fees represented the largest item of school expense, accounting for more than half of the total. Next in importance came equipment and supplies, for which the average student spent almost a third of his school funds. Books accounted for less than 7 percent, and the remainder was spent on such items as fraternity dues and examination fees.

School expenses were rarely distributed evenly over the 4 college years. In the majority of reporting schools, expenditures reached their peak in the sophomore year and then declined; in many cases, school costs in the senior year were no more than half the amount recorded in the peak year. This uneven distribution was generally caused by the timing of major purchases of equipment and supplies. Some students substantially reduced total school expenses by renting, rather than purchasing, much of the needed equipment.

School costs in private schools were greater than those in public schools. Most of the difference was attributable to charges for tuition and fees, which were 45 percent higher in private colleges. In addition, the equipment, supply, and book bill was higher for the private school student.

There were also regional variations in the levels of school expenses. In the Northeast, where tuition and fees were highest, the student spent \$5,113 over 4 years. School expenses averaged \$1,812 in the West, where expenditures for tuition and fees were below the northeastern level, but equipment and supplies were

higher. Average expenditures were \$4,241 in the South and \$4,122 in the North Central States. Tuition and fees were slightly lower in the South than in the North Central States, but equipment and supplies cost more.

Living Costs

Since living expenses amounted to 62 percent of the average student's budget, they were much more important than school expenses in determining the total cost of a dental education. Within the framework of living costs, food and housing required the largest outlays, with food accounting for one-third and housing for one-fifth of all expenditures. Personal maintenance and recreation were other large items, constituting one-fourth of the budget. Health and medical care cost comparatively little, averaging about 3 percent for all students, and many of them failed to list it at all.

Unlike school expenses, living costs increased progressively throughout the 4 years. The upward trend resulted from a combination of gradually expanding expenditures by both married and single students and a progressively larger proportion of married students in each of the higher classes.

Living costs, like school costs, tended to be higher for private school students. The exception to this pattern appears to be the single

school deans, distributed questionnaires to the 12,516 students enrolled in the country's 43 dental colleges. Students were asked to estimate their expenditures for the 1953-54 school year and to designate the source of funds used to meet these expenses. They were also asked to supply information regarding personal and family characteristics, types of living arrangements, and proposed sites of future practice.

Survey schedules were returned by all of the 26 privately financed schools and by 13 of the 17 publicly financed schools. Enrollments in these 39 colleges amounted to about 90 percent of the entire student body. Of the 4 nonreporting public schools, 2 were located on the Pacific coast and 2 in the North Central States. Schedules were completed by 87 percent of all private school students and 58 percent of all public school students, for a total participation of 76 percent. The data pertaining to the characteristics of students and to their financial problems are summarized here.

A Changing School Population

The present dental school population is in a phase of transition. The veteran enrollments marking the immediate postwar period are now on the decline, and as a result there has been a lowering of the average age level of dental students as well as a decrease in the number of married men among the student population.

Despite the downward trend in average age, today's students are still older than their prewar counterparts and are more likely to be married. They enter school with more predental education than their predecessors. The majority are from families whose annual incomes are well above the national average, and their fathers are likely to be in professional or managerial occupations.

The occupational background of parents and the level of family income apparently are factors influencing the choice of dentistry as a career. One in every nine students has a dentist father; nationally, 1 in every 500 men in the labor force is a dentist. Only about one-third of all dental students are from families with annual incomes of less than \$5,000, an income group represented by four-fifths of the families in the United States.

Among dental students from low-income families, the proportion of veterans, who are eligible for financial assistance under the GI bill, is relatively higher than the proportion of nonveterans. The GI bill has proved to be a patent factor in stimulating enrollments of qualified students from low-income groups.

Cost of Dental Education

In estimating expenditures for the 1953-54 academic year, dental students were asked to list both school and living expenses. School expenses included amounts spent either by the student or on his behalf for tuition and fees, textbooks, instruments, equipment and supplies, organization dues, and other related expenses. Living expenses covered sums paid for rent, food, clothing, recreation, personal maintenance, health services, travel, and miscellaneous expenses of the students and any dependents in their households. Students living with parents or friends listed only their out-of-pocket expenses for these items.

Annual expenses reported by the different categories of students in each of the four classes in school in 1953-54 were projected as 4-year totals in order to estimate the complete cost of a dental education.

A review of these estimates shows that the cost varies from student to student and from school to school. The differences in the levels of total expenditures are largely the result of variations in living expenses, which range over a wide scale of values while school expenses fluctuate only moderately. The highest average school costs reported by any category of students are only one-fourth greater than those at the lowest level, but the highest average living expenses are six times as great as those at the lowest level (see figure). The most striking differences in living expenses are those associated with marital status and living arrangements, factors having no appreciable effect on the levels of school expense (table 1).

School Expenses

For the student body as a whole, the average cost of 4 years in dental school was \$11,814. Of this amount, \$7,349 covered living expenses,

re accurate measure of the amount student pays for his education than average for all single students. His expenses averaged \$4,428 and were higher than those of the married student's living costs, which totaled \$5,913, percent less. Food bills were \$2,115, though this was far below the amount of the married student, it represented a share of total expenditures (36 percent). Housing was also cheaper, averaging 10 percent). He was able to devote a larger budget to personal maintenance and dividing nearly \$1,800 between the expenses for health and medical care and only \$77 for the 4 years.

Cost of education for the single student with his parents was \$8,295, the lowest recorded for any category of student. For this student alone, school expenses were higher than living costs. School expenses, which averaged \$4,697, were also higher than those of other students, primarily because a larger proportion of students who were enrolled in private schools paid more for tuition and fees. However, school costs were not only much lower than those of other students but were distributed in a different way. The total living expenditures

for 4 years were \$3,598, or about \$300 more than a married student with children paid for food alone. The largest item of living expense was recreation, which cost \$900 (25 percent) while his out-of-pocket expense for food and lodging combined was \$960 (27 percent). He devoted a larger share of his budget to personal maintenance than other students did.

Source of Student Income

The dental student drew most of the money required to finance his education from sources within his own family. He supplemented these amounts with funds from other sources—scholarships, loans, or benefits available under the GI bill. This was true of both the married and the single student, though they differed in the extent to which they utilized each source (table 2).

The married student relied more heavily on his wife's earnings than on any other type of assistance. If there were no children in the family, her earnings covered more than half of all his expenses. Most of the remainder came from his own earnings and personal savings and from sums supplied by his parents. The presence of children in the household made drastic changes in this financial pattern. His

student who lived at home while attending dental college, presumably because somewhat smaller shares of living costs were reported as expenditures.

Regional variations in living costs did not affect all categories of students in the same way. Costs were highest in the West for the married student (\$10,626) and the single student living away from home (\$6,203). The South was most expensive for the single student living at home (\$4,146).

The greatest variations in the levels of living expense are the result of marital status and housing arrangements, and for this reason the cost involved in seeking a dental education is much greater for the married student than for the single student, and the single student away from home has more expense than the student who lives with his parents.

The Married Student

At the time of the study, about 44 percent of the students were married, and nearly half of these had children. The proportion of married students increased progressively from 31 percent of the freshman class to 63 percent of the seniors. Since marital status is associated with age, it is not surprising that relatively more veterans were married than nonveterans. Two-thirds of the veterans in the freshman class were married; by the senior year, the proportion was 3 out of 4.

Among nonveterans, one-fifth of the freshmen were married; the proportion increased to 50 percent by the senior year. The fact that so many of the nonveterans are married men is an important factor in the future planning of housing facilities. Although the proportion will decline with the withdrawal of the veterans from campus, the number of married students is likely to remain well above the pre-war level and perhaps at the current figure for nonveterans. Schools should therefore plan for a relatively large proportion of married students as a permanent part of dental school enrollments.

For the married student, the total cost of 4 years in school averaged \$14,452. His school expenses amounted to \$1,410, a figure very close, to the all-student average. However, living

expenses, which totaled \$10,042, were more than \$2,500 above the figure for all students, and over \$4,000 higher than the amount spent by single students living away from home. Most of the added expense could be traced to the higher cost of food and lodging.

Seven out of eight married students had established their own home either in houses or apartments, and the cost was two and one-half times as great as that for single students away from home. Food bills were from 25 to 50 percent higher. Purchases associated with furnishing and maintaining a home resulted in miscellaneous expenditures 4 times as great as those of the single student.

The presence of children in the home did not bring any substantial increase in overall costs for the married student, although certain differences in the allocation of expenditures developed. Where there were no children, the average cost of housing was \$2,479, or about 25 percent of all living expenses, and food purchases required \$2,637 (27 percent). For the student with children, food bills rose to \$3,259 (32 percent) and less was spent for housing (\$2,354 or 23 percent). The presence of children meant larger outlays for health and medical care, which rose to \$592, while the childless student spent only \$313. The added cost for health services for the student with children was offset by his lower expenditures for personal maintenance and recreation. Because of this tendency to meet higher expenses in one area with lower expenses in another, total living costs for the married student with children averaged only \$444 more over 4 years than those of the student who had no children.

The Single Student

Fifty-six percent of all dental students were single. One out of four of them lived at home while attending school, and by doing so substantially reduced the cost of their education. The remaining 75 percent had accommodations in dormitories and fraternity houses on the campus or in rooms and apartments nearby.

The student living away from home had total expenditures averaging \$10,341, and since this amount reflects essentially the total cost of all items of school and living expense, it pro-

Modern Methods in Preventive Medicine

Striking evidence of the application of modern methods and viewpoints in preventive medicine appears in the three papers presented on the following pages. They were given at the third annual meeting of the American College of Preventive Medicine on November 14 and 15, 1956, held in conjunction with the 84th annual meeting of the American Public Health Association, Atlantic City, N. J.

As the scientific, sociologic, and economic horizons have widened in this country, so have public health needs and potentials. A group which can testify to this from direct experience includes physicians actively engaged in or concerned with public health at the State-community level. From such a group evolved the impetus that resulted in the founding of the American College of Preventive Medicine, a professional organization stressing scientific development and application to public health.

The American College of Preventive Medicine is a relatively new society, comprised of physicians trained and active in the fields of preventive medicine and public health. It was officially organized in April 1954. But its real beginnings lie in the early days of the Association of State and Territorial Directors of Local Health Services, which had as one of its primary objectives the organization of the American Board of Preventive Medicine. Through the conjoined efforts of this and other professional associations, this objective was accomplished in 1949.

In a short time the idea began to develop among the diplomates of the board that an organization similar to the colleges or academies composed of specialists of other disciplines should be set up. Dr. George A. Dame, then president of the Florida Academy of Preventive Medicine as well as of the Association of State

and Territorial Directors of Local Health Services, took the initiative in bringing together a large group of interested diplomates to consider the question. This meeting in April 1954 resulted in the founding of the American College of Preventive Medicine. Among its objectives are:

- To maintain and advance the highest possible ideals and service standards in education, practice, and research in preventive medicine and public health.
- To encourage and aid medical colleges in establishing a systematic method of teaching preventive medicine and public health . . .
- To encourage, promote, and support the several schools of public health in the universities.
- To stimulate development of residency training centers in preventive medicine and public health.
- To support development and strengthening of sound local health departments to serve all populations and areas in our country.
- To enhance and maintain the interest of practicing physicians in preventive medicine and public health, and to further their training in these specialties.
- To promote the positive health of the individual and of the community.

The college works closely with the American Board of Preventive Medicine in developing and approving residency training programs and is active in improving intraining opportunities for public health personnel and in many other areas of its specialty. It has moved ahead rapidly along the lines of its objectives, and membership early in 1957 totaled 783 fellows. Each member is required to be a diplomate of the American Board of Preventive Medicine.

wife's earnings then provided only a quarter of his expenses. To make up the deficit, the student dipped deeper into his savings, and the amount he earned while attending school almost doubled. His parents increased their contribution by nearly a third, and he added to this by almost tripling the amounts he borrowed. Aid received from scholarships also increased.

Both categories of single students received most of the money which paid for their education from their parents and supplied the remainder from personal savings and earnings. Parents supplied about 59 percent of funds for the student away from home and 52 percent for the student living at home. However, since the student at home was instructed to list only his own out-of-pocket expenses, the aid this student actually received from his parents would generally be much greater than these percentages indicate.

Veterans' benefits comprised only 6 percent of total funds for all students, but they made a substantial contribution to the funds of students who received them. The average amount received from this source by different categories of students varied; for the married veteran with children the benefits covered a sixth of his total costs, and for the single veteran who lived with his parents, they covered about a seventh.

Scholarships and loans were other sources of funds which were of more importance to individual students than they appear to be when averaged for an entire category of students, and the amounts obtained from them were greater for married students with children than for any other group.

Indebtedness

In spite of the substantial financial assistance received from various sources, 57 percent of all dental students were in debt by the time they were graduated. Fourteen percent owed \$6,000 or more, 23 percent owed between \$2,000 and \$5,999, and another 20 percent, amounts less than \$2,000. The size of the indebtedness rose progressively over the 4 years in school, with

the average debt per student increasing from \$2,193 to \$4,230 between the freshman and senior years.

Conclusion

The cost of a dental education is so high that no category of students, married or single, was able to provide as much as half of total expenses from personal savings and earnings. Most students depended upon wives or parents for the major portion of their funds, and many of them went deeply in debt. For some students, particularly for those from low income groups who could not expect substantial aid from their families, the GI bill covered a large share of the costs of education. Other equally effective programs of financial aid would obviously make available to the dental profession a reservoir of capable students at a time when there is a growing need for qualified practitioners.

It should also be emphasized that despite the changing composition of the current dental student body and the gradual withdrawal of the veteran from the campus, married students will continue to make up an important segment of future enrollments. The especial needs of these students in terms of housing and other campus accommodations should be a major factor in planning future school facilities. Provisions for adequate, low-cost housing for married students would do much to solve their particular financial problems.

selects only those patients for whom he feels he can ethically accept the alternatives. Once he has decided to include a patient, treatment is assigned in the central office by a system of random numbers, and the patient is treated with the assigned medication for a specified period. This is a critical point in the studies: a system in which treatment is assigned by persons who have no knowledge of the patient. It eliminates any influence, conscious or unconscious, which physicians treating the patient might exert on the assignment of treatment regimens. Not only is this method simpler for the physician responsible for the care of the patient but it is also the only sure way of obtaining groups of patients that are alike at the moment the different chemotherapeutic regimens are started. Thus, any subsequent differences between the groups can be attributed to the effects of chemotherapy.

Only in two exceptional circumstances is treatment altered: if a patient develops an intolerance to one or more of the assigned drugs or if his disease becomes critically worse, threatening his life.

The number of patients in a study ranges from 541 in the first cooperative effort, with 12 participating hospitals, to 1,990 in one of the more recent trials, with 29 hospitals. The size of these studies insures that the results are unlikely to be due to chance variation. In addition, it permits examination of the influence of various factors, such as age, race, and sex of the patient and stage and extent of disease, on the response to treatment.

In this era of bigness the impression is sometimes created that numbers alone are enough. But a definitive study depends only partly on size. These studies have also been carefully designed with these points in mind: What are the critical questions? What observations will provide the most information? How can these observations be made most objective and accurate?

Random allocation of treatment provides treatment groups completely comparable at the beginning of a study. By several other devices we try to obtain objectivity and freedom from bias in measuring the effects of treatment.

In testing for bacterial resistance, for example, sputum cultures are first examined in

each hospital laboratory by technicians who are not allowed to know the patient's treatment. All positive cultures from all hospitals are sent to one central laboratory not associated with any of the hospitals. There each culture is tested for drug sensitivity without the bacteriologist's knowing the patient's regimen. In every study, many cultures are tested for sensitivity to drugs that the patient is not even receiving. The results of these cultures provide valuable information on the validity of the other results.

In the interpretation of X-rays, as another example, duplicate X-rays of each patient are taken monthly. One is kept at the hospital and one is sent to the central office. Periodically, the participating clinicians meet in Washington to review all the films. The serial films for each patient are read independently by three readers who do not know the patient or his treatment regimen. Each reader interprets the films for an equal number of patients on each regimen from every hospital except his own.

We shall now review briefly the nine cooperative studies carried out since 1947, tracing the evolution of tuberculosis chemotherapy and highlighting the results of the studies. In each subsequent study, new regimens are tested against the regimen which has previously given the best results. A summary of the studies is presented in figure 1.

Streptomycin and PAS

In the first study streptomycin was tested against no chemotherapy. A randomly selected half of the 541 patients received the classic treatment of bed rest, diet, and surgery, while their counterparts in each hospital received, in addition, streptomycin for the first 3 months of a 12-month observation period. Physicians in the 12 hospitals participating in this investigation deserve credit for their courage in carrying through a study in which streptomycin was withheld from half their patients.

By every criterion, patients who received streptomycin for 3 months were in better condition after 12 months than were the controls. Seventy percent of the streptomycin patients showed X-ray improvement, as compared with only 45 percent of the controls. Cultures were

Chemotherapy of Tuberculosis, Progress and Promise

THE DECLINE in tuberculosis mortality in the United States, which began in 1910, has been sharply accelerated during the past 10 years. Tuberculosis deaths dropped from 40 per 100,000 in 1945 to about 10 in 1955. Although this drop may be due in part to a slight decrease in new cases and perhaps in some measure to earlier detection of the disease, it must be primarily a result of improved treatment. Without question, the greatest single factor in the improvement of treatment has been the development of antimicrobial agents active against the tubercle bacillus.

Adequate assessment of the new drugs required new methods in clinical research. Aside from the knowledge about what could be expected of various antimicrobial agents, the most significant result of the evaluation of tuberculosis chemotherapy was the evolution of the large-scale, centrally coordinated, cooperative control study. The pattern developed for this type of study has elements necessary for evaluation of any treatment, in tuberculosis or in other diseases. A review of the therapy trials of the Public Health Service will not only summarize the present position of the chemotherapy of tuberculosis but will illustrate the scope and possibilities of such studies.

The Public Health Service first became engaged in evaluating tuberculosis treatment in

1947, when it acted as the central office for a control study of streptomycin. Congress had made special funds available for testing this antibiotic, the first to show marked antituberculous activity in the test tube and in animals. To avoid possible repetition of the disappointment and disillusionment that followed the high hopes raised by previous "wonder" treatments, such as gold, it was necessary to test streptomycin in such a way that the great desire to find an effective drug would not influence the appraisal of its efficacy. Therefore, it was decided that the available funds should be spent largely on control studies carried out in a number of hospitals throughout the country.

To date, the Public Health Service cooperative group has undertaken nine studies on tuberculosis therapy. Tuberculosis clinicians in hospitals in all parts of the country have voluntarily pooled their facilities and case material to carry out carefully designed control studies. This cooperative arrangement provides wide geographic representation, which gives a picture of variations in the disease and its response to treatment in different parts of the country. The Public Health Service has organized the studies, provided detailed protocols, assigned treatment regimens, coordinated the work in the participating hospitals, analyzed the data, and provided financial assistance to the hospitals to meet the special study expenses.

Each clinician relinquishes some autonomy in treating patients he places in a study. But he is aware of the exact limits of the restrictions because he himself has helped to plan the study. Knowing that any patient placed in the study may by chance receive any one of the regimens to be investigated, the clinician

This paper was presented before the American College of Preventive Medicine by Dr. Rufus Payne, Medical College of Georgia, Augusta, one of the clinical investigators in the Public Health Service tuberculosis therapy trials. It was prepared by Shirley H. Ferebee and Dr. Frank W. Mount, Tuberculosis Program, Division of Special Health Services, Public Health Service.

tion that isoniazid must be compared in strict control studies with the best therapy then available, that is, streptomycin plus PAS. Consequently, in that same month, representatives of 22 tuberculosis hospitals met in Washington and adopted a common protocol to evaluate the therapeutic efficacy of isoniazid. Within 5 months 1,535 patients were under observation.

In the course of these investigations, bacteriological change had emerged as the most sensitive index of the effectiveness of antimicrobial agents. In the charts to follow, bacteriological results of various regimens are compared for previously untreated patients who were infectious when they were admitted to the studies.

Isoniazid

Since the second study had shown streptomycin plus PAS to be superior to streptomycin alone, we used streptomycin plus PAS in the third study as the yardstick against which to measure isoniazid alone and isoniazid in combination with streptomycin. For all regimens the decrease in positive cultures was rapid during the early weeks of treatment. By the 40th week, however, cultures were still positive for 39 percent of the patients treated with streptomycin plus PAS and 38 percent with isoniazid alone, but for only 25 percent with isoniazid plus streptomycin (fig. 2).

Having found isoniazid plus streptomycin superior to either streptomycin plus PAS or isoniazid alone, we proceeded to a fourth study, which included 1,799 patients. We used isoniazid plus streptomycin as the basic regimen and compared it with isoniazid plus PAS and with all three drugs together, isoniazid plus streptomycin plus PAS. We also investigated the possibility that better results might be obtained by increasing the daily dose of isoniazid from 3 mg./kg. to 10 mg./kg.

The three regimens with 10 mg./kg. of isoniazid were about equally effective in reversing infectiousness (fig. 3). At the end of 40 weeks of treatment, tubercle bacilli were detected in the cultures of 17 percent of the patients treated with isoniazid plus streptomycin, in 8 percent treated with isoniazid plus PAS, and in 6 percent treated with all three drugs. Although

there was no therapeutic advantage when the dose of isoniazid was raised from 3 to 10 mg./kg., the 10 mg./kg. dose was considerably more toxic, producing peripheral neuritis in about 10 percent of the patients. On the basis of these findings, we reasoned that the regimen of choice at that point was isoniazid at 3 mg./kg. plus PAS, which would leave streptomycin to be used later if necessary.

Switching Regimens

In all these studies bacteriological changes were rapid during the early weeks of treatment, but patients still producing positive sputum after the 20th to 24th week seldom became negative. This observation led to the fifth study, in which major drugs were switched after 24 weeks of treatment and different sequences tried. For the first 24 weeks we gave half the patients isoniazid plus PAS and half streptomycin plus PAS. Then we switched half the patients receiving isoniazid plus PAS to streptomycin plus PAS and half those receiving streptomycin plus PAS to isoniazid plus PAS.

During the first 24 weeks, when half the 1,990 patients were receiving isoniazid plus PAS and half streptomycin plus PAS, the decrease in positive cultures was greater with isoniazid plus PAS (fig. 4). By the 24th week cultures

Figure 2. Percentage of patients with positive cultures during 40 weeks of treatment with streptomycin plus PAS, isoniazid, or isoniazid plus streptomycin.

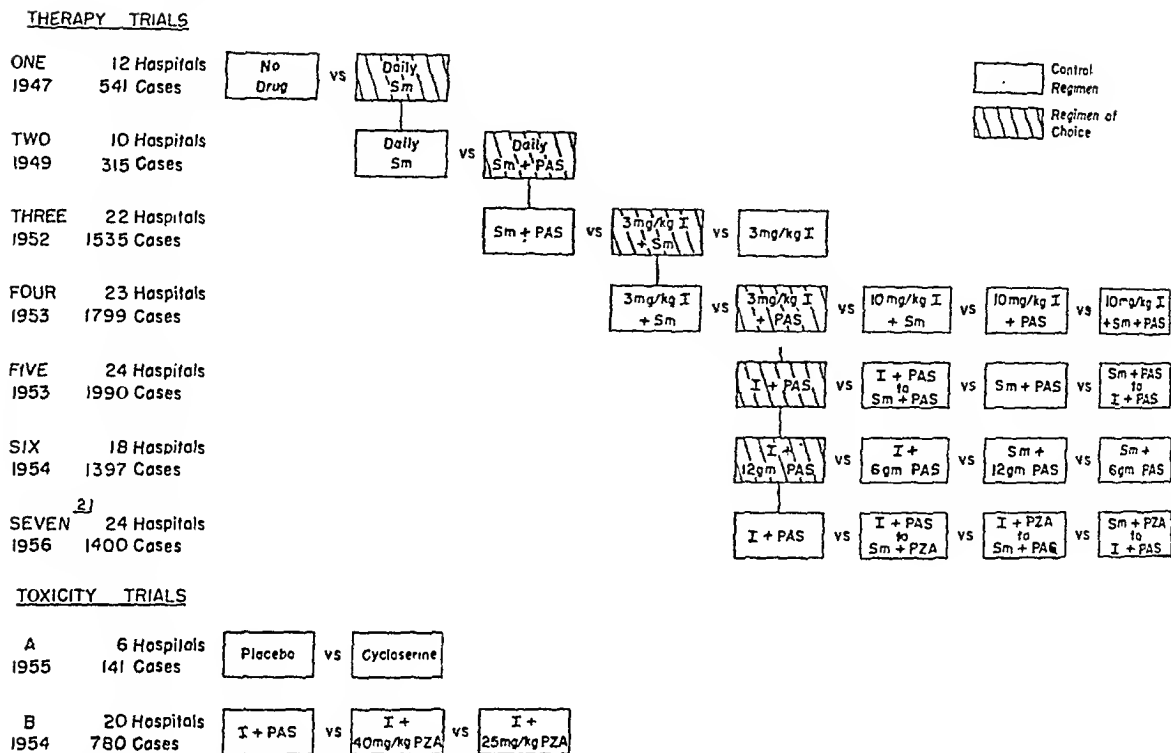

Figure 1. Summary of the Public Health Service tuberculosis therapy trials.¹

¹ Unless otherwise specified, Sm (streptomycin) was given in doses of 1 gm. 3 times a week; I (isoniazid), 3 to 5 mg./kg. daily; PAS (para-aminosalicylic acid), 12 gm. daily; and PZA (pyrazinamide), 40 mg./kg. daily. Cycloserine was tested in four dosages: 0.5 gm. twice a day, 1.0 gm. every second day, 0.5 gm. once a day, and 0.25 gm. twice a day.

² In progress.

negative for 24 percent of the streptomycin patients but for only 16 percent of the controls. The most striking finding in this first study, however, was that streptomycin halved the number of deaths: Only 10 percent of the streptomycin patients, as compared with 20 percent of the controls, died during the year of observation.

Shortly after streptomycin was introduced, PAS (para-aminosalicylic acid) became available in this country. With the usefulness of streptomycin clearly evident, the cooperating group decided its second study should compare streptomycin alone with streptomycin plus PAS. Since PAS showed much less tuberculostatic activity than streptomycin in the test tube and experimental animals, it was not thought necessary to include a group receiving only this drug. Each of 315 patients was randomly assigned to receive either streptomycin or streptomycin plus PAS for 3 months,

with observation to continue for another 3 months. The primary purpose was to see whether PAS might prolong the usefulness of streptomycin by delaying the emergence of streptomycin-resistant organisms. It was found that not only did PAS prolong the streptomycin sensitivity of the tubercle bacilli, but it increased the frequency of sputum conversion and resulted in greater X-ray improvement.

By 1952 the price of a gram of streptomycin had fallen from \$20 to about 20 cents, and the drug was available in plentiful supply, as was PAS. The two drugs together had become the standard treatment for hospitalized tuberculosis patients throughout the United States. They were indispensable adjuncts to bed rest and surgery in the long-term care necessary for tuberculosis patients. Then in March 1952 isoniazid made its dramatic entrance. In the midst of tremendous enthusiasm for the new drug, the Public Health Service took the posi-

of PAS with isoniazid, we also used this opportunity to test a lower dose of PAS with streptomycin. We randomly divided the 1,397 patients into 4 groups to receive daily isoniazid with 12 grams of PAS, isoniazid with 6 grams of PAS, streptomycin with 12 grams of PAS, and streptomycin with 6 grams of PAS.

This study demonstrated that PAS toxicity was reduced by decreasing the daily dose. During the 40 weeks of treatment about 11 percent of the patients could not tolerate the 12 gram dose, but only 4 percent could not tolerate 6 grams. Most of the patients who could not tolerate the larger dose were able to continue the drug when the dosage was cut in half.

In combination with either isoniazid or streptomycin the large dose of PAS was slightly more effective than the small dose (fig. 6). Again, the combination of isoniazid plus PAS was superior to streptomycin plus PAS. In fact, even the small dose of PAS with isoniazid was more effective than the large dose with streptomycin.

We concluded that all patients should be placed first on a regimen of isoniazid plus 12 grams of PAS. However, for those unable to tolerate that dose of PAS, the daily dose

Figure 5. Percentage of patients with positive cultures from the 24th through the 40th week among patients treated continuously with streptomycin plus PAS or switched from streptomycin plus PAS to isoniazid plus PAS after 24 weeks and among patients treated continuously with isoniazid plus PAS or switched to streptomycin plus PAS after 24 weeks.

Figure 6. Percentage of patients with positive cultures during 40 weeks of treatment with isoniazid plus 6 gm. PAS, isoniazid plus 12 gm. PAS, streptomycin plus 6 gm. PAS, or streptomycin plus 12 gm. PAS.

could be reduced to 6 grams with only a small loss in therapeutic effectiveness.

Cycloserine and Pyrazinamide

Up to this point, we had been investigating ways of using the three available drugs, isoniazid, streptomycin, and PAS. In the past 2 years we have considered, in addition, two other antimicrobial agents, cycloserine and pyrazinamide. Both drugs had been reported to produce severe toxic reactions. Therefore, before testing their therapeutic efficacy in previously untreated patients, we undertook studies among "hopeless cases" to determine the frequency and severity of the toxic reactions.

In one toxicity study we compared several different doses of cycloserine with a placebo. No significant toxic reactions occurred among the 26 patients receiving placebos, but toxic reactions to cycloserine occurred at all dose levels tested except the lowest, which we found to be below the range of therapeutic effectiveness (see table). Convulsions, the most serious of the toxic effects, were not confined to a single dosage, and we found no evidence that they were limited to patients with certain characteristics. Therefore, in contrast with the safety and effectiveness of isoniazid

had become negative for all but 26 percent of the patients on streptomycin plus PAS and for all but 8 percent of the patients on isoniazid plus PAS. Patients whose cultures had not become negative may be regarded as treatment failures, and their course during the subsequent 24 weeks is reported here.

The treatment failures included patients who died of tuberculosis or whose chemotherapy was changed because of critical worsening, as well as those who continued to produce tubercle bacilli after 24 weeks on the primary regimen. Of course, for those who died there was no opportunity for the secondary regimen to change the course of their disease, and for those whose treatment was changed earlier the status at the 24th week is not a measure of the effect of 24 weeks of treatment on the assigned regimen.

The left chart in figure 5 deals with the 26 percent of the streptomycin-plus-PAS patients who had failed to become sputum negative, including 4 percent who had died or been removed from the regimen. When treatment with streptomycin plus PAS was continued, the failure group decreased to 20 percent by the 40th week. However, when isoniazid plus PAS was substituted for streptomycin plus PAS, the proportion of bacteriological failures dropped to 10 percent by the 40th week.

Figure 3. Percentage of patients with positive cultures during 40 weeks of treatment with isoniazid plus streptomycin, isoniazid plus PAS, or isoniazid plus streptomycin plus PAS.

Figure 4. Percentage of patients with positive cultures during 24 weeks of treatment with streptomycin plus PAS or isoniazid plus PAS.

The right chart in figure 5 deals with the 8 percent of the isoniazid-plus-PAS patients whose cultures had not become negative by the 24th week. This group includes 1 percent who had died or had been changed to another treatment regimen. When treatment with isoniazid plus PAS was continued, the percentage of failures dropped to 4 by the 40th week. When treatment was switched to streptomycin plus PAS, the results were no better.

This study showed isoniazid plus PAS to be such an effective regimen that there was little advantage in switching to streptomycin plus PAS after 24 weeks. On the other hand, among patients initially treated with streptomycin plus PAS, a switch to isoniazid plus PAS after 24 weeks was preferable to an additional 16 weeks of streptomycin plus PAS.

Decreased PAS Dosage

Again isoniazid plus PAS appeared to be the regimen of choice both for initial and long-term use. However, it had always had one disadvantage. A number of patients were unable to tolerate the usual large dose of PAS, 12 grams a day. Encouraged by the results of a small pilot study, we decided to see whether decreasing the dose of PAS would reduce toxicity without loss of therapeutic effect. Although we were primarily interested in the use

States, San Juan, Mexico City, and Toronto. Each child takes pills for 1 year, and neither the patient, nor his family, nor the physician knows whether the pills contain isoniazid or placebo. By comparing the number, kind, and severity of complications that develop among children taking isoniazid with the complications that develop among children taking placebos, we expect to determine isoniazid's effectiveness.

In the meantime we are accumulating information to answer an even more basic question: How often today do meningitis and other complications of primary tuberculosis occur? In

other words, we are collecting precise information on how much there is to prevent, by isoniazid or any other preventive procedure.

The next step in the Public Health Service's investigation is to determine whether isoniazid will prevent infection and the appearance of clinical disease among the highly exposed household contacts of active cases of tuberculosis. A nationwide study is being started in which contact households are randomly assigned to isoniazid or placebo groups and are kept under close observation by their local health departments. Each contact is tuberculin tested and X-rayed at the beginning and at

Clinical Investigators in the Tuberculosis Therapy Trials

The following 53 physicians in 39 hospitals scattered throughout the United States participated in the Public Health Service tuberculosis therapy and toxicity trials conducted from 1947 through 1956. The figures and letters in parentheses are trial designations, as given in figure 1.

Baltimore City Hospital, Baltimore, Md.: Edmund G. Bencham (7).

Batley State Hospital, Rome, Ga.: Rufus Payne (2,3,4) and Raymond Corpe (4,5,6,7,B).

plus PAS, we concluded that cycloserine was too toxic for us to undertake a large-scale therapeutic trial in patients with a favorable prognosis.

Pyrazinamide had been reported to have a dramatic therapeutic effect when used with isoniazid but to cause acute liver damage in some patients. In a carefully controlled study among 780 treatment failures, we used isoniazid plus PAS as a control and tested 2 doses of pyrazinamide in combination with isoniazid. Liver function tests were carried out in the hospital laboratories by technicians who did not know what drugs the patients were receiving, and the patients were examined for signs and symptoms of hepatitis by physicians who had no knowledge of their treatment.

During the first 12 weeks of treatment, evidence of hepatic toxicity was reported for 0.8 percent of the patients receiving isoniazid plus PAS and for 0.8 and 1.2 percent of the patients receiving, respectively, 40 mg./kg. and 24 mg./kg. of pyrazinamide with isoniazid. During the second 12-week period liver damage appeared among 5.4 percent of those receiving the larger dose of pyrazinamide and among 1.2 percent of those receiving the smaller dose. These findings, plus the fact that the treatment failures had shown considerable therapeutic benefit from the combination of isoniazid and pyrazinamide, made us decide to undertake a large-scale therapeutic trial of pyrazinamide in combination with isoniazid and in combination with streptomycin. However, we are using pyrazinamide for only 16 weeks and are then switching regimens. This study was be-

gun only recently, and it will be some months before results will be available.

Prophylactic Possibilities

For those of us concerned with preventive medicine, interest in the treatment of persons with active pulmonary tuberculosis is not confined to the direct benefits to the patients. We are sensitive to an indirect benefit from improved treatment: the decrease in spread of disease. More infectious persons are willing to accept treatment, and infectiousness is reversed in most of those treated.

Now, isoniazid introduces the possibility of a new method of tuberculosis control: prophylaxis. It is a cheap, orally administered drug that has been demonstrated during the past 4 years to be extremely effective in the treatment of patients with tuberculosis and to be practically nontoxic in therapeutic doses. A drug that can reverse the course of far-advanced cavitary disease might, if given at the right time, prevent the appearance of clinical disease.

Prophylaxis in tuberculosis has become a highly controversial subject. Some enthusiasts advocate immediate widespread use of the drug in highly exposed population groups. Others are equally firm in their conviction that such use of isoniazid would have grave consequences by interfering with the development of natural immunity. But there is also a middle ground, one occupied by many physicians and public health workers. They feel, as does the Public Health Service, that only a series of large, long-term, controlled investigations can provide actual data to replace the present spate of conjecture on the effects of using isoniazid to prevent clinical tuberculosis in human beings.

The Public Health Service and a number of cooperating clinicians and public health workers have begun a series of studies on the prophylactic possibilities of isoniazid. In the first study in human beings, the prophylactic goal is the prevention of meningitis and other complications among children with asymptomatic primary tuberculosis whose present condition does not require treatment. More than 2,000 children are now under observation in 31 pediatric clinics in the continental United

Public Health and the Social Sciences

By HENRY VAN ZILE HYDE, M.D.

PUBLIC health physicians and their professional colleagues have an implied responsibility for assisting peoples of the world to improve the shape of their affairs. Let us consider what the world role of public health may be and how the social sciences may be of use in playing it.

The social sciences occupy a strange place in the world of learning. They are not quite accepted in the parlor, but it is being increasingly recognized that they are cooking something promising in the kitchen. James B. Conant, struggling in his Terry lectures with the question of the place of the social sciences on today's scene, concludes that perhaps the social scientist should be considered a social philosopher and points out what a sterling word "philosopher" really is. Alfred North Whitehead, considering the place of science in the modern world, finds a tendency for the natural sciences to fall into grooves and to miss the necessary comprehension of man's life among men. Despite the great accomplishments of the natural sciences, we have, he says, no expansion of wisdom, when we are in greater need of it than ever before.

Do the social sciences, as a philosophy in the original Greek sense, perhaps fit into the niche that is vacant? Do they, in dealing with the problems of man's relation to man, somehow provide, or at least promise, a bridge between the coldness of the test tube and the warmth of human feelings?

The social sciences consist only of attempts to apply known techniques of observation, experimentation, and logic to man's total be-

havior as a rational and emotional animal, and to the groups through which he acts and relates himself to others. They are attempts to look at human feelings through the test tube.

Again, as in the case of the natural sciences, grooves form: psychology, social psychology, sociology, economics, anthropology, and so on. Knowledge today is so vast that it must be organized. It is necessary to make certain that such organization does not create intellectual iron curtains. Rather, it must create bridges between areas of thought and knowledge.

Science proceeds by the formulation and testing of concepts, amending, enlarging, and replacing them as fact and experience, seen through the glass of wisdom, may dictate. The social sciences may, because of the material with which they deal, be expected to develop broadening concepts dealing with man's relations with man, concepts which when institutionalized may lead to a richer life. The United Nations did not arise full-formed, Venus-like from the sea, but is the institutionalization of concepts that have developed and progressed through the centuries. Thucydides, in fact, set the philosophical and political stage for the United Nations when he said that discussion does not block action but is the only precursor to action that wisdom can allow.

On the basis of what we have seen of the social sciences to date, should we be frustrated and throw up our hands in despair? Raymond Fosdick, in his thoughtful treatment of the social sciences in the Story of the Rockefeller Foundation, says that "unless we find successful solutions to some of the intricately complex and fast-growing problems of human relationship, we run the risk of having a world in which public health and medicine are of little signifi-

Dr. Hyde is chief of the Division of International Health, Public Health Service.

the end of a year of prophylaxis. Included in the study population are both uninfected (tuberculin negative) members of the household and infected (tuberculin positive) members who show no clinical evidence of disease. The study should provide information on the effectiveness of isoniazid in preventing new infections and in preventing development of clinical disease in those already infected. Because this study includes a group that gets only placebos, it will also provide information on just how much tuberculosis is arising today among household contacts of the tuberculous.

In still another branch of this investigation, isoniazid's effect among previously infected persons who are not in highly exposed situations will be studied. An impressive body of evidence is accumulating that much of the new clinical tuberculosis is occurring among previously infected persons whose subclinical infection progresses to active disease under either

external stress or decreased general resistance. It seems most important to determine whether the threat of tuberculosis which millions of older persons infected in childhood carry with them can be removed by prophylactic use of isoniazid.

This difficult and costly investigation may show that isoniazid has no prophylactic value, or that its value is offset by interference with natural immunity, or that it is effective only while it is being taken. It may show that it only delays but does not prevent. On the other hand, if it is effective in any one of the areas under investigation, in preventing infection, in preventing new infection from progressing to clinical disease, or in eradicating old subclinical infections which may flare up in endogenous disease, we will have gained an important public health weapon in the fight against tuberculosis.

Cerebral Vascular Disease Program

The first nationwide cooperative research program on cerebral vascular disease was launched in April 1957.

Ten medical research centers in 9 States have joined in the program, and it is expected that 35 to 40 institutions will eventually participate. The program, which is under the auspices of the National Institute of Neurological Diseases and Blindness of the Public Health Service, was made possible by grants from the National Institutes of Health to the various participating organizations. The program is supplemented by 29 current research projects on various aspects of cerebral vascular disease.

Cooperative investigation will make possible the study of thousands of patients who either have suffered a stroke or who show clinical signs indicating that a stroke might be approaching. The program is specifically concerned with patients suffering from cerebral vascular disease involving hemorrhage, blood clots, blood tumors, (aneurysms), and malformations of the arteries or veins of the brain.

Research results may reveal more about the nature and causes of strokes and facilitate more effective treatment methods.

Data collected will be collated and evaluated at the University of Iowa, Iowa City, one of the cooperating institutions.

Understanding the Individual

What are these forces that we need to understand? One is the behavior of individuals in settings of various complexities. What are the forces that influence the individual? This may not seem relevant when we are considering the world stage, but it is. The world is run by human beings, each an individual shaped by a multitude of antecedent forces. Often the individual is lost in the vastness of the action that he has taken or influenced, but all world actions are the result of the component forces at work on the world stage, and those forces are transmitted through individuals and modified by transmission. Personal pique and animosity, emotional reactions, individual blind spots play their role internationally as they do at home, affecting the course of history.

At Versailles, after World War I, Masaryk, the father of Czechoslovakia, was one of the great leaders. He was known for his wisdom, his ideals, and thus was able to give leadership and direction to the shaping of the new Europe. Only on one point did he become irrational and obstructive. He insisted upon the inclusion within Czechoslovakia of a small nipple of land that projected beyond the proposed borders of Czechoslovakia into what was logically a part of Poland. Why did he do this? Because his birthplace, his hometown, lay within that area. Thus it is men who make the events of history and men that need to be understood. Public health deals with men and has a chance, perhaps, to understand men and thus to enable them to understand themselves.

The problems of the community tend to stand out in progressively bolder relief the farther we move from our own culture, setting aside, as we do, the blinders of our own experience and our own emotional involvements. For this reason and because of my particular international orientation, I take an example from abroad, in the expectation that we may see analogies in our own communities, to indicate the complex skein of forces that interweave within a community.

Sindbis is a crowded, squalid Egyptian village. The streets are narrow, muddy, and laden with refuse. The Rockefeller Foundation addressed itself to the problem of improving health in this village and worked there for 3

years. It was easily demonstrated that infant mortality and therefore general mortality could be sharply reduced by the application of insecticides to control the flies. This, though, was a temporary measure, the flies becoming rapidly resistant to the insecticides. The demonstration pointed to the absolute necessity of improving sanitation if anything significant were to be accomplished.

An Egyptian home is a mud-walled compound off of which open 2 or 3 small, unventilated rooms; a rickety stairway goes up to similar small rooms above. In crowded villages such as Sindbis, the compound is often roofed-over by the upper rooms. In the compound, which measures perhaps 10 by 10 feet, there dwell, in addition to the family, a gamoose (a water buffalo), a sheep or two, and several chickens. These are occupying what to you and me is the living room. In the corner is a pile of dung cakes. The floor is carpeted by the accumulated dung of decades. Meals are cooked over an open fire in a corner of the compound. It would appear that health education in its simplest forms might readily solve such obvious problems. But let's look at some of the factors concerned.

Sindbis is built upon some of the most precious land in the world. In Egypt, on 13,000 square miles of arable land, 23,000,000 people, 1,800 people per arable square mile, are attempting to eke out an existence. It is not possible for Sindbis to expand laterally over such precious land, nor, since the only available building material is mud or sun-dried brick, can it extend vertically. A second story is risky; a third story, impossible. On May 12 and 13, 1945, rain in parts of the Delta, the only rain I ever saw in Egypt, washed away such villages as this.

If we cannot provide better housing within the locally available resources, then we can at least clean out the dung. But this approach also presents problems. The dung is one of the family's most important assets, both for fertilizer and for fuel. It cannot be risked outside but must be kept under guard.

Then let us move the animals out. Did you ever suggest to your own family the possibility of getting rid of your own dog? The eyes of a gamoose, I can testify, are infinitely more

cance." He further cautions against impatience in this difficult task, saying, "The impatient analogy between the spectacular progress of public health and medicine and what could conceivably be accomplished by the social sciences is basically unsound. Human emotions and prejudices, unlike human diseases, do not yield easily to rational solutions. We can look forward to no mechanistic answers which will automatically solve the problems of human adjustment. The assumption has to be made that there is time for intelligence to take hold, and students of society have to presuppose the opportunity for long-maturing work." The Rockefeller Foundation and more lately the Ford Foundation are betting hundreds of millions of dollars on this assumption.

The Relation to Public Health

How does this relate to public health? to members of the profession?

Public health is in a unique position in relation to man and his communities. It is also an activist cult, the self-imposed business of which is to change man's behavior. Because of its opportunity and its activities, public health has an obligation to study, within its own field of vision, the processes that affect man's behavior. We are the high priests of an activist cult. We must accept the responsibilities of priesthood, unless we are to become practitioners of a stultified priestcraft such as served their own purposes under the protecting wings of Amen-Ra in far-off times. We must learn not only how, but whether and when to activate. The social sciences offer the best available avenue for the exploration of the city of fact and relationship in which each of us lives—to obtain a better comprehension of the community of man and how best to modify it in the interests of man.

The trouble of our times, great in scope and profound, is based on man's failure in governing his relationship to himself. The connection with public health may appear at first glance to be loose and remote. Such is not the case: Health today is not on the periphery of history but at or very near its center. In the most populous areas of the world where

the masses are sick, it is one of the major factors affecting man's relationship to himself and to his environment.

One phase of the role of public health in the world today is its modification of man's relationship to himself and to his environment. This modification initiates chain reactions in the social and economic spheres, the end of which is not always, if ever, in sight. Public health has, for instance, launched a vast malaria eradication program, with a view to eliminating the 300 million cases of malaria that once occurred each year. A number of countries, including our own, have already attained the objective of eradication, and the world goal is not an impossible one. Can we foresee the ultimate effects on mankind of such a change? We know it will have effects on man's ability to produce. It will provide increased labor in the fields during planting and harvesting time; it will open up new lands; it will make man more alert and educable. Yes, and it will increase the population where populations are already dense. These changes will in turn have their own effects, and these can be foreseen but dimly.

The world can never again be what it once was. Asia, particularly the areas in the tropics and semitropics and the Middle East, and Latin America are not the same as they were even a short time ago. Their relationships with other more advanced parts of the world in northern Europe and North America are changing, and will change, deeply and fundamentally. Health has a causal relationship to this great historical change. This we cannot avoid, but we can try to understand it and to lead it in a direction that is right by our moral view.

The second phase of the role of public health stems from its peculiarly close association with man and the community. Here is the opportunity for public health to add to the understanding of the human processes that make history. Historic events are due to the working in the macrocosm, the world, of forces that are also at work in the microcosm of our own communities. These forces can be isolated, analyzed, and understood with more precision in the microcosm. On the larger stage they are often lost in the very vastness of the scene.

this be the case, it is possible to understand the points of difference and to prepare to meet and reconcile them.

Profound problems arise, problems we can only suggest in this presentation. For example, is action always to be preferred over apathy? F. S. C. Northrop of Yale, Edmund Taylor in his *Richer by Asia*, and many others have considered how we might attain some profitable fusion of the philosophies of the East with those more characteristic of the West, a reverse point 4 in philosophy perhaps. They suggest that a more intensive search for karma or nirvana might modify the intensity of the search for space and substance, for land and dollars. Such questions have their social and economic implications which are subject to analysis and indeed measurement in economics, which is perhaps the most adult of the social sciences.

If we accept a wholly activist philosophy, then action must be purposeful and the purpose, as well as the results of attainment of the purpose, must be examined. Purposes often seem self-evident. We accept the urgent need for rapid economic development as a truism. But Munoz-Marin, the Governor of Puerto Rico, who has given such magnificent leadership to Operation Bootstrap which has raised Puerto Rico from a slum to a guiding star of progress, has recently offered a tantalizing suggestion. He has proposed an Operation Serenity, through which society "would use its economic power increasingly for the extension of freedom, of knowledge, and of the understanding imagination rather than for a rapid multiplication of wants." When asked how he would accomplish Operation Serenity he said, "I have let a bird into the air."

Avenue of the Social Sciences

Public health must consider how best to address itself to these matters. As already suggested, the social sciences provide the main avenue of the present for applying to these great social problems the techniques and concepts which have carried us so far in the natural sciences, in the hope, of course, that new and special techniques and concepts of a fundamen-

tal character will emerge, in the hope that the social sciences will have their Galileo, their Newton, their Darwin—or will it be a Michaelangelo or a Milton?

The field is being plowed. A number of schools of public health have social scientists on their staffs.

The Health Information Foundation in the 1955 edition of its *Inventory of Social and Economic Research in Health* listed 398 active research projects.

The Social Science Research Council has established the Committee on Preventive Medicine and Social Science Research, which is attempting, slowly but with steady progress, to identify and direct attention to areas requiring fundamental research. Shortly, it plans to begin the publication of documents emerging from its discussions with specialists in a number of fields.

A separate but closely related development of first importance is the creation of the Joint Committee on Public Health and the Behavioral Sciences by the American Public Health, Anthropological, and Psychological Associations and the American Sociological Society. This committee is attempting to lower the barriers existing between the public health professions and the social sciences through the organization of campus seminars, workshops, and newsletter abstracts and other publications.

Summary

Public health physicians have at hand in their own communities on a manageable scale the problems of human and community relations which are today harassing the world. At the same time social scientists in increasing numbers are at hand, on neighboring university campuses, in business enterprises, and in departments of government. Thus the tradition of team work in public health need not be stretched far in an effort to delve thoughtfully and deeply into these problems. The answers found will be a part of the storehouse of knowledge and concept that must lead through these troubled times into a more orderly future.

soulful than even those of a basset hound. There is a deep emotional, as well as economic, attachment to the gamoose. He is part of home and he has been so through the ages. Herodotus in 500 B. C. wrote, "All other men pass their lives separate from animals; Egyptians have animals always living with them."

Thus, in attempting to activate the people of Sindbis, we immediately run into economic considerations of the greatest moment, long-established habits and cultural patterns, and sociological problems.

Universality of the Basic Forces

The same basic forces operate in every community. We would not have a gamoose in our homes, but we do have dogs. Dogs are carriers of rabies, hydatidosis, and flukes whereas, as far as I know, the gamoose is quite an innocent beast. Despite this, we cannot view a dog with the same objectivity with which we view a gamoose.

Herodotus helps us establish the fact that this blindness is not a new thing. He tells us: "Thus it appears certain to me, by a great variety of proofs, that Cambyses was raving mad; he would not else have set himself to make a mock of holy rites and long-established usages. For if one were to offer men to choose out of all the customs in the world such as seemed to them the best, they would examine the whole number, and end by preferring their own; so convinced are they that their own usages far surpass those of all others. Unless, therefore, a man was mad, it is not likely that he would make sport of such matters. That people have this feeling about their laws may be seen by very many proofs: among others, by the following. Darius, after he had got the kingdom, called into his presence certain Greeks who were at hand, and asked what he should pay them to eat the bodies of their fathers when they died. To which they answered that there was no sum that would tempt them to do such a thing. He then sent for certain Indians, of the race called Callatians, men who eat their fathers, and asked them, while the Greeks stood by, and knew by the help of an interpreter all that was said, what he should give them to burn the bodies of their fathers at their decease. The Indians ex-

claimed aloud, and bade him forbear such language."

We can easily overlook in our own environs what might be obvious aberrations when viewed dispassionately by an outsider, unless we apply the critical tools of science to our own behavior and that of our own communities. The answers to the problems of Sindbis are yet to be found, but we have in our own community the laboratory in which the basic principles involved may be better understood.

What are some of these matters as we face them in our own communities?

The cult of success drives us Americans inexorably towards the vice-presidency of the firm. En route we deposit in our arteries great hunks of cholesterol, consumed at feasts paid for by a grateful firm. Or we build up a great head of pressure striving to be foreman of the gang, principal of the school, or State health officer, ignoring what we know, or think we know, of the dangers to our gastric mucosa. This is cultural pressure, our own culture. Can we modify the culture or adjust man to it? Do we preach laziness and apathy? Do we give tranquilizing drugs? Or is there some other way? Daily we drive headlong to our own destruction on the highways. You know this grim story, but who of us has never bragged of the speed he made on some trip? Our culture commends us, if only we keep out of jail. Coronary disease is not all chemistry, and highway safety is not all engineering. They involve man and his behavior in a cultural setting.

The problems of convincing communities to fluoridate water, or parents to bring only certain of their children for a widely touted vaccine, or a woman to palpate her breasts when horror struck that she might feel a fatal lump are examples of problems here at home that have in them, somewhere, answers to fundamental problems of men's relations and motivations.

I have been deeply impressed through the years with the sameness of motivations and responses among people of widely differing cultures. The differences to a large extent are superficial. Being exotic, they tend to impress us overmuch. Members of this college deal almost daily with colleagues from other lands. I trust you find a deep sameness in them. If

strated to be carcinogenic and to affect the genes. Genetic effects can be created with relatively light doses. The significance of such effects, however, is far from being completely evaluated.

Epidemiological studies are contributing to our knowledge of radiation effects. For example, physicians experience an incidence of leukemia 1.75 times as great as males in the general population (5). March has shown that the incidence of leukemia among nonradiologist physicians is 0.44 percent, while the incidence among radiologists is 4.47 percent (6). More recently, preliminary analysis of data from a survey of 547 children dying of leukemia and other malignant diseases in England during the period 1953-55 definitely indicates these conditions are most frequent among those whose mothers had X-ray examinations of the abdomen during pregnancy (7, 8).

Potential Effects of Radiation

The following explanation of what may happen when body tissue is irradiated, though greatly simplified and undoubtedly controversial from a technical viewpoint, is useful in discussing radiation injury.

Ionizing radiation produces within a body cell one or more pairs of electrically charged fragments called ions. The number of cells affected depends on the time and intensity of exposure, the volume of tissue exposed, and the character of the radiation. Radiation from external sources is relatively less consequential than radiation from sources lodged in the tissues.

Following the production of ions in a cell, an ion pair may simply recombine or other ion combinations may form. The former event is of little concern, but the latter may cause either alteration or destruction of the cell. Destruction of the cell may contribute to the phenomenon of aging, and the only result will be a shortening of the life span. Alteration of the cell may produce either a benign or a malignant mutation. A benign mutation is not of great concern in a somatic cell, but it could be important in a genetic cell. A malignant mutation may in time form cancerous tissue. Of the potential effects of radiation on body cells then, mutation is most important.

When tissues are exposed to any amount of ionizing radiation, some or all of these effects are possible. Even minimal exposure or background exposure from natural sources contributes to the probability of an untoward effect. Therefore, the theoretical goal in prevention of radiation injury should be limitation of exposure to the absolute minimum.

The National Research Council reports attribute an average accumulated dose of about 4.3 roentgens of external radiation over a 30-year period to background radiation not under man's control; 3 roentgens to the gonads from X-rays; and a projected 30-year external exposure from fallout from testing of weapons, if continued at present levels, of about 0.1 roentgen. (The probable internal exposure is not included in these calculations.) To these exposures must be added potential occupational exposures and exposures from diagnostic or therapeutic uses of radionuclides.

Medical exposure can be controlled by laboratory techniques and equipment put to judicious use. Occupational exposures can most certainly be approached from the viewpoint of preventive medicine.

The Armed Forces have two broad areas of interest in ionizing radiation protection. These are (a) the problems associated with nuclear weapons and reactors and (b) those not directly so associated. In the Army, the Surgeon General has a special assistant for nuclear energy, who deals primarily with tant. Matters pertaining to microwave hazards in medical radiology are within the purview of the chief radiological consultant. Matters pertaining to microwave hazards, nonmedical and nonweapons uses of emitters, and radiological hygiene surveys of Army installations are charged to the chief of the Preventive Medicine Division and are delegated to the Occupational Health Branch. In the newly developing field of nuclear reactors, all these people have important interests.

Scope of the Army's Problem

All of the Army's 1,025,000 military and about 435,000 civilian employees have radiographs taken as part of their preenlistment or preemployment physical examinations. Many

Preventing Injury From Radiation

By JOHN R. HALL, Jr., M.D., M.P.H.

INJURY from ionizing radiation is a phenomenon which, with the advent of nuclear physics, has squarely challenged practitioners of preventive medicine. The everyday uses of ionizing radiation from various natural and man-made emitters can result in low-level, chronic exposure, if not in inadvertent high-level exposure. Exposure to doses well below dramatic levels can result in slowly developing and currently irreversible adverse biological effects in present and future generations. At this time, virtually the only approach to limiting this potential toll is through preventive medicine. After-the-fact therapy is not now promising (1).

Rather than present an abstract, general discussion of radiation control, I should like to describe the policies and practices of the Army Surgeon General and his staff, which are applied daily throughout the world. The Army is keenly aware of the activities and contributions of other agencies and works closely with them. The Atomic Energy Commission, always a leader in this field, provides us with much information and guidance, and there are many projects that are joint endeavors of AEC and the Armed Forces. In addition, the National Bureau of Standards and the National Research Council, as well as other agencies, play important roles.

Early Medical Concern

The Army's concern with the problem of radiation injury is based on medical history since

Colonel Hall, in the Medical Corps of the U. S. Army, is chief of the Occupational Health Branch, Preventive Medicine Division, Office of the Surgeon General, Department of the Army.

Roentgen discovered X-rays in 1895, Becquerel discovered natural radioactivity in 1896, and the Curies isolated polonium and radium in 1897-98. That the potentially harmful effects of radiation were suspected early is borne out by the following quotation from American Martyrs to Science Through the Roentgen Rays (2): "Within a period of 90 days after Roentgen's 'Preliminary Communication,' suspicion was aroused in the minds of many investigators that X-rays, or something evolved in the production of X-rays, might have some ill effect on living tissues . . ." Becquerel accidentally burned the skin beneath his vest pocket in which he was carrying a vial of radium. The Curies, too, were burned by radium, Marie accidentally and Pierre deliberately as an experiment. And, as is well known, the deaths of Madame Curie and her daughter, Irène Joliot-Curie, have been attributed to effects of radiation. Madame Joliot-Curie was exposed in a laboratory accident, when she heroically attempted to confine the contents of a broken vial of an intensely active element while she warned her co-workers to flee.

Early concern with radiation injury has been augmented by continuing developments in fundamental and applied radiobiology. Recent reports of the National Research Council (3) concerning biological effects of radiations, which are closely paralleled by a report of the British Medical Research Council (4), have sharply emphasized the need of preventive action. The National Research Council reports describe the potentially harmful effects of ionizing radiation on this generation and on its posterity, thereby touching upon both the somatic and the genetic effects. They stress the cumulative aspects of chronic exposure, especially genetic. Ionizing radiations have been demon-

Protection of Army Personnel

Army regulations require individual dosimetry, or inventory, for all personnel in an environment heavily exposed to ionizing radiation (13). Accurate cumulative records must be kept in a manner prescribed by tri-service regulation (14). In continental United States, Army installations receive film badge service from the Lexington Signal Depot (15), which provides the badges and the film on an appropriate periodic schedule. Exposures above 300 milliroentgens per week are reported to the installation and to the Surgeon General by telegram or telephone. If gross or multiple over-exposures are indicated, technicians are sent to the installation to help pinpoint and correct the difficulty.

Many believe that the Army control measures are more severe than those of civilian counterparts. If so, it is only in adherence to common sense and to existing standards and regulations. We scrupulously observe the Atomic Energy Commission's requirements. We use the data of the various National Bureau of Standards handbooks, some of which we have borrowed wholly or in part and reissued as Army bulletins and directives. When newer information dictates or suggests modifications in these data, we publish and enforce the changes. We also issue publications specially developed for the Army.

The Army attempts to learn and comply with State and community requirements. In that respect, two pleas are in order. First, when regulations for a State or a locality are issued, we ask health officials please to send copies to the surgeons general of the three services. Second, we ask everyone to remember that the control of ionizing radiations is important to national health. As in motor vehicle or air control, maximum standardization of codes, symbols, marking, regulations, and restrictions is desirable. The practices of New York State, where National Bureau of Standards handbooks and related or similar documents and procedures are used extensively, are exemplary in this respect.

Summary

The Army's main concern with respect to prevention of radiation injury is the protection of

the individual against unnecessary exposure to ionizing radiation. We consider all ionizing radiations to be potentially harmful. Our approach is essentially preventive. We try to foresee the hazards, design protective facilities and procedures, keep accurate records of users and uses, provide maximum protective and monitoring devices at each installation, and then check by disinterested survey to assure local competence and adherence to prescribed procedures and to detect hazards otherwise overlooked. National and local monitoring and investigation of noteworthy exposure support this effort.

receive additional exposure to X-rays in emergency or periodic examinations. The Army also operates induction stations for the three services. These activities employ hundreds of X-ray installations throughout the free world. These installations, utilizing a variety of machines acquired at various times and initially installed by various agencies and companies, are periodically serviced, calibrated, moved, and checked for radiological hazards. Although some of the work is done by operating personnel, the "disinterested" survey method also is used. This type of survey is conducted by personnel from the Army Environmental Health Laboratory, with the aid of outstanding consultants as necessary.

Six large Army hospitals use radionuclides for medical research and treatment, and a large number of laboratories, arsenals, and industrial-type installations use radioelements in nonmedical research and development, production, and training. Some sources used by the Army are in the order of tens and hundreds of curies in strength. All these must be monitored and surveyed periodically.

All Army users of radionuclides receive them through the standard byproduct procedures established by the Atomic Energy Commission (9), with the important exception that all requests must be transmitted through the Office of the Surgeon General. For approval by the Army Surgeon General, a request must show that proper receiving, handling, storage, and disposal facilities and adequately trained and experienced personnel are available. These trained persons assume responsibility for the radionuclides and supervise their use. The Army has excellent rapport with AEC and, in a sense, acts as its agent, although visiting AEC teams are always welcome to conduct checks on the Army's operations, either independently or in conjunction with our personnel.

Disposal of radioactive wastes, a responsibility of the Army Chemical Corps (10) with technical advice and supervision from the Surgeon General, is a major problem. Morton and Struxness of the Atomic Energy Commission have pointed out that it may well prove to be one of the limiting factors in achieving optimum benefits from nuclear energy (11). Relatively minute quantities of short half-lived

radionuclides may be admitted to the sewage system where this practice is allowed and under strict controls. Larger amounts may be stored in appropriate receptacles pending loss of activity. Among other methods tried or studied are burial at sea below the thermocline, at a depth of a thousand fathoms, after casting into concrete or incorporation into an insoluble ceramic mass; ground disposition in certain soils having available ion exchange patterns; and disposition in such natural containment formations as the salt formations in Michigan and Kansas, the regional aquifers in the midwest and the southwest, and the closed valleys in the west.

The Army also has betatrons, industrial X-ray machines, and high-activity radionuclides for industrial radiography or for processing military items. Some radionuclides are being used with considerable success for sterilization of packaged foodstuffs. The Army uses appreciable quantities of naturally occurring radionuclides, such as radium, over which the Atomic Energy Commission now extends no control. The Army has established administrative controls for these materials similar to those for other radioactive substances (12).

In cooperation with the other armed services and the Atomic Energy Commission, the Army is now moving into the nuclear reactor field. Our first reactor, water moderated and designed to develop electric power and heat, has recently been completed at Fort Belvoir, Va., near Washington, D. C. This reactor, because it is near a population center, is in a building designed, according to AEC standards, to contain fully any contamination from radionuclides. The design conforms also with recommendations of the National Research Council (3a).

An ultimate goal for the Army in this field is an easily transported or even mobile reactor to provide heat and power in remote areas of the world where logistics of conventional fuel supply are burdensome and costly. Currently, the Army is on the threshold of this goal with a stationary prototype and can be expected to move rapidly into various applications with the accumulation of knowledge and experience. The Army Medical Service expects medical problems from power reactors to grow and is preparing for that eventuality.

Identification of Two Leptospiral Serotypes New to the United States

By MILDRED M. GALTON, DOROTHY K. POWERS, STURGIS MCKEEVER,
and GEORGE W. GORMAN

RECENTLY, two leptospiral serotypes not found previously in the United States were isolated from the kidneys of wild animals collected in southwest Georgia (1). The identity of these two serotypes, one a member of the *mitis-hyos* serogroup, the other belonging to the *australis* A serogroup, is recorded in this paper.

Relatively few leptospiral serotypes have been isolated in the United States, probably because of the limited number of medical and veterinary laboratories providing appropriate diagnostic service. *Leptospira icterohemorrhagiae*, the first serotype isolated in this country, was obtained from wild rats in 1917 (2) and from man in 1922 (3). Since that time, four other serotypes, *Leptospira canicola* (4, 5), *Leptospira pomona* (6-8), *Leptospira autumnalis* Fort Bragg (9), and *Leptospira ballum* (10), have been identified in the United States. Serologic evidence has indicated that infection with strains related to *Leptospira bataviae* (11), *Leptospira sejroe* (12, 13), *Leptospira grippotyphosa* (14), and *Leptospira pyrogenes* (15) may exist, but these serotypes have not been isolated.

The authors are with the Communicable Disease Center, Public Health Service. Mrs. Galton, of the Epidemiology Branch, is bacteriologist in charge, Leptospirosis Research Laboratory, Chamblee, Ga. Mrs. Powers, now retired, was formerly a bacteriologist with that laboratory. Dr. McKeever, a biologist, and Mr. Gorman, a bacteriologist, are with the Technology Branch and are assigned to the Newton Field Station in Georgia.

Four of the cultures of leptospirae included in this study were isolated from the kidneys of opossums trapped on two plantations in Baker and Dougherty Counties, Ga., in September and October 1955. These were designated LT79, LT81, LT82, and LT85. Two additional cultures, designated LT95 and LT102, were isolated from the kidneys of two raccoons trapped on a plantation in Decatur County, Ga. All cultures were tested first against immune sera of *L. autumnalis*, *L. ballum*, *L. canicola*, *L. icterohemorrhagiae*, *L. pomona*, and *L. sejroe*, the usual battery used to test leptospiral isolations received from the Communicable Disease Center field station in Newton, Ga., and then with immune sera representative of the remaining 14 serogroups.

Procedures

Preparation of antisera. Immune sera were prepared by intravenous inoculation of normal rabbits weighing 8-9 lbs. with successive doses of 1.0-ml., 4.0-ml., 4.0-ml., and 6.0-ml. amounts of a 4- to 6-day-old culture of each leptospiral strain grown in Stuart's medium (16) and killed by the addition of 0.3 percent formalin. The 4 injections were given at 5- and 7-day intervals. Seven days after the last inoculation the rabbits were bled from the heart. Serum yield averaged 75 ml. per rabbit. After the addition of 50 percent glycerine as a preservative, the sera were stored at 40° F.

Preparation of antigens. Leptospiral strains used for antigen production were maintained in

technical publications

Health and Demography

PHS Publication No. 502. 1956. By Halbert L. Dunn, M.D. 94 pages; illustrated. 50 cents.

Population trends and developments pertinent to present and future public health programs have been collated in this graphic presentation.

The condensed data are presented in five sections: the dynamics of population trends in the United States; population trends for major geographic areas and States; population characteristics; age and marital status; economic status and indicators of health and disease. A foreword and a postscript present the views of the author.

Directory of State Standard-Setting Authorities for Hospitals and Medical Facilities

PHS Publication (unnumbered). 10 pages. 1956.

This publication entitled "Directory of State Agencies Having Primary Legal Responsibility for Standards of Maintenance and Operation of Hospitals, Nursing Homes, Homes for the Aged, and Other Similar Facilities Except Those Operated by Federal and State Governments" briefly shows in tabular form the responsibilities of various State

agencies administering or licensing seven types of medical facilities. An accompanying index lists names and addresses of these agencies.

Intended as an aid to State, local, and other health agencies in planning and administering their programs, this pamphlet was published by the Division of Hospital and Medical Facilities (administering body of the Hill-Burton Hospital and Medical Facilities Survey and Construction Program).

Industrial Waste Guide to the Commercial Laundering Industry

PHS Publication No. 509. 1956. 8 pages; illustrated. 15 cents.

Intended primarily to aid workers in the water pollution control program, this handbook was prepared by the Stream Pollution Abatement Committee of the American Association of Textile Chemists and Colorists in cooperation with the American Institute of Laundering. It was submitted for publication to the Public Health Service through the National Technical Task Committee on Industrial Wastes.

Laundry supervisors will find this publication a concise practical guide for operation of washrooms with a minimum of waste material. A section on waste treatment suggests possible solutions to stream pollution which cannot be corrected by waste reduction procedures. Some

performance data are included on various waste treatment processes. The value of waste reduction methods in lowering total waste treatment costs also is emphasized.

The Circulatory System Illustrated Guide for Nursing Education

PHS Publication No. 482. 1956. 67 pages; illustrated. 35 cents.

Designed for nursing education in cardiovascular disease, this booklet contains 20 colored diagrammatic figures with explanatory text.

This guide is also intended as a timesaver for nursing school instructors, for individual nurses, and for staff education in hospitals, industry, and public health agencies.

The schematic drawings used are reproductions from the set of colored slides on the circulatory system, produced in 1954 by the Public Health Service, and used widely in nursing education.

This section carries announcements of all new Public Health Service publications and of selected new publications on health topics prepared by other Federal Government agencies.

Publications for which prices are quoted are for sale by the Superintendent of Documents, U. S. Government Printing Office, Washington 25, D. C. Orders should be accompanied by cash, check, or money order and should fully identify the publication. Public Health Service publications which do not carry price quotations, as well as single sample copies of those for which prices are shown, can be obtained without charge from the Public Inquiries Branch, Public Health Service, Washington 25, D. C.

The Public Health Service does not supply publications issued by other agencies.

Identification of Two Leptospiral Serotypes New to the United States

By MILDRED M. GALTON, DOROTHY K. POWERS, STURGIS McKEEVER,
and GEORGE W. GORMAN

RECENTLY, two leptospiral serotypes not found previously in the United States were isolated from the kidneys of wild animals collected in southwest Georgia (1). The identity of these two serotypes, one a member of the *mitis-hyos* serogroup, the other belonging to the *australis* A serogroup, is recorded in this paper.

Relatively few leptospiral serotypes have been isolated in the United States, probably because of the limited number of medical and veterinary laboratories providing appropriate diagnostic service. *Leptospira icterohemorrhagiae*, the first serotype isolated in this country, was obtained from wild rats in 1917 (2) and from man in 1922 (3). Since that time, four other serotypes, *Leptospira canicola* (4, 5), *Leptospira pomona* (6-8), *Leptospira autumnalis* Fort Bragg (9), and *Leptospira ballum* (10), have been identified in the United States. Serologic evidence has indicated that infection with strains related to *Leptospira bataviae* (11), *Leptospira sejroe* (12, 13), *Leptospira grippotyphosa* (14), and *Leptospira pyrogenes* (15) may exist, but these serotypes have not been isolated.

The authors are with the Communicable Disease Center, Public Health Service. Mrs. Galton, of the Epidemiology Branch, is bacteriologist in charge. Leptospirosis Research Laboratory, Chamblee, Ga. Mrs. Powers, now retired, was formerly a bacteriologist with that laboratory. Dr. McKeever, a biologist, and Mr. Gorman, a bacteriologist, are with the Technology Branch and are assigned to the Newton Field Station in Georgia.

Four of the cultures of leptospirae included in this study were isolated from the kidneys of opossums trapped on two plantations in Baker and Dougherty Counties, Ga., in September and October 1955. These were designated LT79, LT81, LT82, and LT85. Two additional cultures, designated LT95 and LT102, were isolated from the kidneys of two raccoons trapped on a plantation in Decatur County, Ga. All cultures were tested first against immune sera of *L. autumnalis*, *L. ballum*, *L. canicola*, *L. icterohemorrhagiae*, *L. pomona*, and *L. sejroe*, the usual battery used to test leptospiral isolations received from the Communicable Disease Center field station in Newton, Ga., and then with immune sera representative of the remaining 14 serogroups.

Procedures

Preparation of antisera. Immune sera were prepared by intravenous inoculation of normal rabbits weighing 8-9 lbs. with successive doses of 1.0-ml., 4.0-ml., 4.0-ml., and 6.0-ml. amounts of a 4- to 6-day-old culture of each leptospiral strain grown in Stuart's medium (16) and killed by the addition of 0.3 percent formalin. The 4 injections were given at 5- and 7-day intervals. Seven days after the last inoculation the rabbits were bled from the heart. Serum yield averaged 75 ml. per rabbit. After the addition of 50 percent glycerine as a preservative, the sera were stored at 40° F.

Preparation of antigens. Leptospiral strains used for antigen production were maintained in

Stuart's medium and transferred twice weekly. Such actively growing seed cultures were used in approximately 1:10 to inoculate the desired amount of Stuart's medium in screw-capped prescription bottles. The inoculated bottles were incubated 4-5 days at 28°-30° C. and then examined by dark-ground microscopy for density and smoothness. If the antigens appeared satisfactory, 0.3 percent formalin was added, and they were allowed to stand overnight at room temperature. They were centrifuged for 10 minutes at a speed of 1,500× gravity (about 3,000 r.p.m. on a No. 1 International Centrifuge) to remove debris or precipitate. The supernatant was decanted and was then ready for use.

Agglutination test procedure. Serial two-fold dilutions of serum in 0.85 percent saline, starting with 1:8 through 1:32,768, in a final volume of 0.2 ml. were prepared. To each serum dilution, 0.2 ml. of antigen was added. The tubes were shaken, incubated in a water bath at 52° C. for 2 hours, and then refrigerated for 1 hour. A drop from each tube was examined by dark-ground microscopy using low-power objective, and 10× oculars without a coverslip. The degree of agglutination was read as 1 plus, 2 plus, 3 plus, 4 plus, or negative. A reaction was recorded as 4 plus when all leptospire appeared clumped, 3 plus when approximately 75 percent of the organisms were agglutinated, 2 plus with 50 percent agglutinated, and 1 plus with 25 percent agglutinated. The end point was taken as the last dilution showing a 1 plus reaction.

Agglutinin absorption procedure. Antigens for absorption studies were prepared from 5- to 6-day-old cultures grown in Stuart's medium and killed by the addition of 0.3 percent formalin. After standing at room temperature overnight, the cultures were centrifuged for 10 minutes at 1,500 × gravity to remove extraneous material. Ten to twenty milliliters of the supernatant were put aside to be used later as antigen for testing the absorbed serum. The remainder of the supernatant was centrifuged for 15 minutes at 9,000 × gravity in a Servall. The supernatant was discarded, and the desired amount of a 1:20 dilution of serum was added to the packed cells. The cells were resuspended using a 2.0-ml. Cornwall pipette

with a 4-inch, 17-gauge needle. After incubation of the serum-cell mixture in a 50° C. water bath for 2 hours and overnight at 28°-30° C., the cells were removed by centrifugation and the serums absorbed a second time by the same procedure but without overnight incubation. If necessary, a third absorption was carried out. Absorptions were considered complete when agglutinins were completely removed by the homologous antigen. Microscopic agglutination tests with the absorbed serums were performed by the procedure described above except that the initial dilution was 1:40.

Findings

None of the cultures in this study agglutinated when tested against the usual battery of leptospiral immune serums.

The mitis-hyos serogroup strains. Culture LT79 was agglutinated by *Leptospira mitis* Johnson antiserum to 25 percent of the titer, by *Leptospira hyos* antiserum to 6 percent of the titer, by *L. bataviae* antiserum to 3 percent of the titer, and by *L. pyrogenes* antiserum to less than 1 percent of the titer. An antiserum prepared against strain LT79 agglutinated to the homologous titer *L. mitis* and *L. hyos* antigens. Cross agglutinin absorption tests performed with *L. mitis* and *L. hyos* indicated that LT79 is closely related to both strains but not antigenically identical with either, as shown in table 1. (A subculture was sent to Col. Maurice Hale, Division of Veterinary Medicine, Walter Reed Army Institute of Research, Washington, D. C., who confirmed our findings.) This new serotype is tentatively designated *Leptospira bakeri*.

According to Wolff (17), the retention of at least 10 percent of the homologous titer is the criterion for heterologous strains. Alexander and his co-workers (18) modified Wolff's scheme slightly to conform to their dilution scheme and considered 6.2 percent ($\frac{1}{16}$ of homologous titer) as the breakpoint for a heterologous serotype.

Culture LT85 also was agglutinated to 25 percent of the titer by *L. mitis* antiserum. It reacted to the homologous titer with LT79 antiserum, and in absorption tests it completely removed the agglutinins for LT79. Absorption

studies indicate that LT79 and LT85 are homologous serotypes.

The other two cultures in this group, LT81 and LT82, appear to be related to the *mitis-hyos* serogroup and to the two new isolates but are not identical with either, as shown in table 2. When LT79 antiserum was absorbed with LT81 and LT82 antigens, these antigens failed to remove the homologous agglutinins by 15 percent. In the initial agglutination tests LT81 reacted to 25 percent of the titer of *L. mitis* antiserum, but LT82 reacted to only 6 percent. Thus, further serologic study is needed to determine the exact relationship of these two strains.

The australis A serogroup strains. Cultures LT95 and LT102 were agglutinated to the homologous titer with *Leptospira australis* A Ballico antiserum. An antiserum prepared against LT95 agglutinated the Ballico strain to 12½ percent of its homologous titer. As shown in table 3, absorption studies revealed that Ballico serum retained 2 percent of its titer when absorbed with LT95 cells, and LT95

serum retained only 1 percent of its titer when absorbed with Ballico cells. Thus, except for minor differences, LT95 is indistinguishable from *L. australis* A Ballico.

Comment

L. mitis was isolated first by Johnson (19) in 1940 in Australia from humans with benign leptospirosis. All patients had been in contact with pigs or cattle. It has been isolated since from pigs (20) in Australia, and serologic evidence suggests that infections occur in cattle. Clinically and epidemiologically, *L. mitis* infection closely resembles *L. pomona* infection.

L. hyos was isolated by Savino and Rennella (21) from humans with mild leptospirosis and from swine in Argentina. Babudieri (22) studied both the *L. mitis* Johnson and the *L. hyos* strains and reported that they were serologically identical. However, further examination of these strains by A. D. Alexander, Walter Reed Army Institute of Research, showed that *L. hyos* is a complete biotype of *L. mitis* Johnson. The results of the present study substantiate Alexander's observations.

L. australis A was identified by Lumley (23) in 1937 from canefield workers in Queensland. Clinical symptoms were reported to be severe. Stagnant water in the canefields yielded the organisms, and a native rat (*Rattus conatus*) was

found to be the principal animal carrier. Recently, two additional strains of the *australis* A serogroup have been found, one in Australia (24) and the other in Malaya, according to Alexander. Further studies with these and with the isolations from raccoons will be done to determine the exact relationships.

The identification of these strains in the United States further emphasizes the importance of serotyping all leptospirae isolated. In addition, inclusion of *L. mitis* or *L. hyos* and *L. australis* A cultures in the battery of antigens employed in the agglutination and agglutination lysis tests in diagnostic medical and veterinary laboratories must now be considered.

Summary

Four strains of leptospirae isolated from opossums, belonging to the *mitis-hyos* serogroup, and 2 strains from raccoons, belonging to the *australis* A serogroup, have been identified. Cross agglutinin absorption studies indicate that the opossum strains are not identical with *Leptospira mitis* Johnson or *Leptospira hyos*, but that they represent at least one new serotype, tentatively designated *Leptospira bakeri*, within the serogroup and possibly one other serotype. Further studies are being done to determine the exact relationships.

Two cultures from raccoons were shown by cross agglutinin absorption studies with *Leptospira australis* A Ballico to be within the range considered acceptable for homologous serotypes.

• • •

Since this work was completed, we have learned of a new serotype of the *mitis-hyos* group. The new leptospiral serotype, designated Kisuba, was isolated in the Belgian Congo (25). The tentative designation of LT79 as *Leptospira bakeri* is suggested until its relationship with strain Kisuba is established.

Advisory Committee

Surgeon General Leroy E. Burney has appointed a committee of physicians to advise him on Public Health Service activities related to the practice of medicine. The first meeting of the new Advisory Committee on Medical Practice Relations was held on April 4-5, 1957, in Washington, D. C.

Dr. Burney said that with the growth of medical and related research, it has become increasingly important to work with private physicians as well as with health agencies in applying new knowledge promptly and effectively.

Members of the committee are Dr. Stuart Adler, Albuquerque, N. Mex.; Dr. C. Byron Blaisdell, Asbury Park, N. J.; Dr. Hugh H. Hussey, Washington, D. C.; Dr. W. L. Porttens, Franklin, Ind.; Dr. Julian P. Price, Florence, S. C.; Dr. Stanley R. Truman, Oakland, Calif.; and Dr. William B. Walsh, Washington, D. C.

found to be the principal animal carrier. Recently, two additional strains of the *australis* A serogroup have been found, one in Australia (24) and the other in Malaya, according to Alexander. Further studies with these and with the isolations from raccoons will be done to determine the exact relationships.

The identification of these strains in the United States further emphasizes the importance of serotyping all leptospirae isolated. In addition, inclusion of *L. mitis* or *L. hyos* and *L. australis* A cultures in the battery of antigens employed in the agglutination and agglutination lysis tests in diagnostic medical and veterinary laboratories must now be considered.

Summary

Four strains of leptospirae isolated from opossums, belonging to the *mitis-hyos* serogroup, and 2 strains from raccoons, belonging to the *australis* A serogroup, have been identified. Cross agglutinin absorption studies indicate that the opossum strains are not identical with *Leptospira mitis* Johnson or *Leptospira hyos*, but that they represent at least one new serotype, tentatively designated *Leptospira bakeri*, within the serogroup and possibly one other serotype. Further studies are being done to determine the exact relationships.

Two cultures from raccoons were shown by cross agglutinin absorption studies with *Leptospira australis* A Ballico to be within the range considered acceptable for homologous serotypes.

• • •

Since this work was completed, we have learned of a new serotype of the *mitis-hyos* group. The new leptospiral serotype, designated *Kisuba*, was isolated in the Belgian Congo (25). The tentative designation of LT79 as *Leptospira bakeri* is suggested until its relationship with strain *Kisuba* is established.

The picture was similar in 1954-55, when only 26 (37 percent) of the 71 available appointments were filled: 21 of the 65 first-year appointments available and 5 of the 6 second-year appointments.

Why so small a percentage of the available residencies are filled is inexplicable. Perhaps too few physicians have been told about the program.

Seattle-King County Program

The Seattle-King County Department of Public Health in Washington has sponsored a residency program in public health since 1952. Our experiences may be of interest to the profession at large as well as to those who are personally involved in postgraduate medical education.

The program adopted by the Seattle-King County Department of Public Health in 1952 began with one resident who, quite literally, had to "play by ear." After completing 1 or 2 months' time in a given service, he selected another for his next assignment. His notes and special studies helped the department to correct some of the deficiencies of the program and to see where the resident would profit by additional supervision or advice. The lack of a basic curriculum was perhaps the worst fault of the first year.

A second candidate, accepted in 1953, left for a residency in surgery before he had finished training. Perhaps we erred in not scrutinizing the intentions and qualifications of the applicant with sufficient care.

States with residencies in public health and preventive medicine, 81 positions, 1956.

Two residents were accepted for 1954. Their work together in activities that consisted mostly of observation and study enabled them to talk over the experiences of the day, make plans for the next week's program, and, when necessary, bolster one another's morale. A schedule assured their spending a definite period of time in each service. During the remainder of the year, the residents were assigned to a district office where they assumed responsibility gradually as their experience and knowledge accumulated. This arrangement proved so satisfactory that two additional residents were accepted in 1955.

Curriculum

The men who have participated in our program as residents have come to us from the hectic and demanding routines of internship or private practice where they were preoccupied with problems of individual patients. To change their professional frame of reference so that they see an entire community as their patient requires time, study, and some degree of personal reorientation as well as specific instruction in technical disciplines. Therefore, the resident's curriculum is designed to present fundamental disciplines of preventive medicine and public health during the first 6 months. At the same time it is sufficiently flexible and leisurely to enable the resident to take advantage of training opportunities that may arise outside the health department, such as special courses at the University of Washington or those sponsored by other agencies, public health meetings, and conferences with visiting experts.

Our curriculum consists of the following four basic subjects:

| | Months |
|-----------------------------------|--------|
| Public health administration..... | 1 |
| Community resources..... | 1 |
| Preventive medicine..... | 2 |
| Environmental sanitation..... | 2 |

Public Health Administration

From the beginning, the director of public health has supervised the residents during their first 2 months in the health department. No one is in a better position to introduce the resi-

Public Health Residency Training

By S. P. LEHMAN, M.D., M.P.H., and D. R. PETERSON, M.D.

I DIDN'T KNOW there was such a thing." We have heard this statement repeatedly from intern and practicing physician alike. The "thing" they refer to is the residency program in public health. While residencies in clinical specialties are well known and accepted, such is not the case in the field of public health. Perhaps this is because the specialty is only about 8 years old. By June 30, 1956, only 1,684 certificates had been awarded in public health.

Residencies for physicians interested in public health as a specialty have evolved since the incorporation of the American Board of Preventive Medicine and Public Health in 1948. The board was formed on the recommendation of a joint committee of the American Medical Association and of the American Public Health Association. It was created in accordance with action of the Advisory Board for the Medical Specialties and was recognized and approved as a medical specialty board by the Council on Medical Education and Hospitals of the American Medical Association in 1949 (1). The purpose of the board is twofold:

- To encourage the study, improve the practice, elevate the standards, and advance the cause of preventive medicine.

- To grant and issue to physicians, duly licensed by law to practice medicine, certificates of special knowledge in the various fields of preventive medicine. The fields in which certification is granted are public health, aviation medicine, and occupational medicine.

Dr. Lehman and Dr. Peterson are with the Seattle-King County Department of Public Health, Seattle, Wash. Dr. Lehman is director of the department, and Dr. Peterson, a former public health resident with the department, is a district health officer.

To be eligible for examination by the American Board of Preventive Medicine, candidates must meet certain general requirements. These pertain to character, professional demeanor, medical education, internship, and medical licensure. Additional requirements for public health candidates are:

1. Successful completion (after internship) of at least 1 academic year of graduate study leading to the degree of master of public health or an equivalent degree or diploma; or training or study decreed by the board to be substantially equivalent to such graduate study.

2. Residency (after internship) of at least 2 years of field experience in general public health practice, which includes planned instruction, observation, and active participation in a comprehensive, organized public health program. 1 year of which may be an approved clinical residency in a field directly related to public health.

3. A period (after internship) of not less than 3 years, in addition to 1 and 2 above, of special training in, or teaching or practice of, public health.

4. Limitation of practice to full-time teaching or practice of public health as a specialty.

In 1955-56 the Residency Review Committee for Preventive Medicine and Public Health (2) had approved residency programs for 2 years of field training in 15 States (see map). In 12 States, 35 local areas were designated as satisfactory for field training; 2 were approved on a statewide basis; and 1 was given provisional approval.

Through a questionnaire sent in September 1956 to all the States known to have a program, we learned that 42 residents had been trained since 1950; 26, or 62 percent, of these residents were doing full-time public health work. Sixty-three appointments were available, but only 19 (30 percent) were filled (see table).

offers the resident insight into the productive teamwork of the astute clinician and the special investigator. The unique records (example: nickname file), the conduct of the clinic, the examination of patients, the special training of the investigators, and the occasional positive dark field examination are some of the highlights of this service.

Environmental Sanitation

A large departmentalized sanitation division affords the residents ample opportunity to see this aspect of public health practice at first hand with a well-qualified person to instruct them. A typical experience in the milk section, for an example, includes an early morning briefing in the main office, followed by a visit to the farm, milk receiving plant, milk processing plant, and then, perhaps, to the laboratory to witness the elucidation of a consumer complaint. Technical factors influencing grade, control of pasteurizing equipment, public relations with milk producers, and a host of other problems are explained. To illustrate the geographic differences in the program, the resident is taken to several areas in this milkshed, which literally surrounds the entire Puget Sound.

This same general type of instruction is given in the other sections: general sanitation, meat, plumbing, plague and vermin control, sewerage installations, and water works. It is in the sanitation division that the resident gets a better view of public health work at its grass roots level than anywhere else.

Completion of Training

Following his indoctrination, the resident is assigned to one of three district health offices situated strategically on the periphery of the metropolitan area. Each district health office serves both a rural and an urban population, with public health problems which are, we feel, representative of those he might expect to meet in the future.

He can confer with experienced personnel on any problem that he feels he cannot solve by himself. Moreover, since his tenure in this post is about 21 months, he has sufficient opportunity

to become established in the community and to learn the elements of public relations which, in our area at present, involve participation with local health councils, municipal organizations of many descriptions, school personnel, radio and newspaper representatives, and similar groups. As often as is practical and within budgetary limitations, this resident, now a district health officer, is encouraged to attend both local and national meetings of public health workers in order that he may better identify himself with this group of medical specialists.

After some 27 months with this health department, the resident attends a school of public health of his own choosing. While at school he is given a monthly stipend as well as tuition and travel funds. When he has completed his academic work and received the master of public health degree, or its equivalent, the resident has fulfilled the formal training requirements of the American Board of Preventive Medicine.

Comments

Inherent in a residency program are features that benefit both resident and health department. How these are integrated into the operation to maintain an equitable balance between values received by each is shown in the inset.

We have been fortunate in getting physician applicants with varied backgrounds. Two had worked in health departments previously, one as a sanitarian and the other as a statistician. Others have come directly from internship, from military service, or from private practice. These men have been intent on making public health a career. Like their counterparts in the clinical specialties, they hope to become accredited specialists in their chosen field. They anticipate training that will enable them to act as consultants to physician and layman alike in medical matters that pertain to the community. The excellent scholastic records of our residents who have matriculated in schools of public health attest to the seriousness of their intentions. We like to feel that careful selection of candidates and broad practical field training contribute to this achievement.

After basic orientation each resident sets his own pace in assuming responsibility for clinics, programs, and planning. However,

dents to the health department personnel, to the community, and to the history, resources, and peculiarities of the area in which they will work.

From the vantage point of the director's office, the residents see the whole operation, though they are not necessarily expected to understand the significance of all that they see during this first exposure. They are included in staff conferences, committee meetings, discussions of personnel problems, hearings before the city council, and discussions of proposed ordinances and other related business of the department, with the anticipation that they will catch the "sense" of what is going on. Inter-staff committee work, writing assignments, helping with correspondence, and similar activities of routine office management help them relate to the organization and feel that they are on the team from the start.

Community Resources

Knowing the community is to the public health physician what knowing anatomy is to the surgeon. Here again the director, with his experience and knowledge, can point out the more important community resources within his jurisdiction. The residents then take the initiative in visiting as many of these organizations as time permits. Among these organizations are other official public health agencies, various volunteer health organizations, industrial medical departments, prepaid medical service organizations, hospitals, group practice clinics, the juvenile court with its satellite service groups, jails, a screening-examination center, and medical rehabilitation facilities. Other governmental organizations, Federal, State, and local, complete the itinerary.

Preventive Medicine

The preventive medicine portion of the curriculum represents more or less familiar ground to the residents and offers them an opportunity to exercise some of the talents developed by their hard-won medical education and experience.

Approximately 3 weeks are devoted to tuberculosis control. Under supervision, trainees participate in outpatient clinics and review the

Status of appointments in 14 public health residency programs, 1956

| Appointments | Number available | Filled | |
|---------------|------------------|--------|---------|
| | | Number | Percent |
| Total..... | 63 | 19 | 30 |
| 1st year..... | 35 | 7 | 20 |
| 2d year..... | 28 | 12 | 45 |

miniature films taken by the various mobile X-ray units. They accompany the State tuberculosis control officer, or his deputies, to other health departments to observe the conduct of outlying clinics and consultations. They are invited to staff meetings at the sanatoriums and are urged to attend whatever professional meetings are being held at the time.

Well-child clinics are held throughout the local health department's jurisdiction. The residents are expected to staff some of these clinics and to familiarize themselves with the type of service offered. Special projects and courses have been devised to help them comprehend the concepts of child health and the significance of morbidity and mortality statistics. Programs for crippled children, for sight and hearing conservation, and for medical care for children are included in their assignments. They are also urged to attend the clinical presentations at the University of Washington or the Children's Orthopedic Hospital and to study the operation of the newly formed poison control center.

Through worn shoe leather and perseverance the aspiring health physician learns the elements of communicable disease control and epidemiology, for he is asked to assume responsibility for making appropriate investigations when indicated. The facilities of all the hospitals that accept communicable disease cases are available in the event of an unusual or interesting case or outbreak. Practical problems of disease reporting, levels of community immunizations, cooperation with other official departments, control regulations and their enforcement, to mention only a few, point up some of the challenges of this aspect of preventive medicine to the residents.

The special case of venereal disease control

Conjunctivitis in Southwest Georgia

By RICHARD P. DOW, Ph.D., and VIRGINIA D. HINES, B.S.

ACUTE CONJUNCTIVITIS, commonly known as "sore eyes," is endemic in various sections of the southern United States. The disease erupts seasonally, reaching high levels of prevalence each summer. Its incidence seems closely related to the seasonal and geographic abundance of "eye gnats" of the genus *Hippelates*. Because of this association, *Hippelates* is not unreasonably considered as a possible vector of conjunctivitis.

The disease occurs mostly in younger children, in uncomplicated cases without any known sequelae. In this country it does not appear to be associated with the spread of trachoma. On the other hand, in a region such as southwest Georgia, where conjunctivitis is endemic, it is a cause of much illness. Most rural preschool children have at least one case of conjunctivitis each summer, and among older children, the disease is a cause of much school absenteeism during the fall (1).

Studies in the Rio Grande Valley in Texas indicated that most cases of sore eyes in that area were due to *Haemophilus aegyptius*, the Koch-Weeks bacillus (2, 3). Additional unpublished studies conducted by Dr. Dorland J. Davis of the Public Health Service demonstrated similar etiology in the vicinity of Thomasville, Ga. Here the Koch-Weeks organism was found to exhibit seasonal abundance corresponding to that of observed sore eyes and

also to occur more frequently than *Haemophilus influenzae* in cultures of eyes having signs of conjunctivitis.

Collection and Analysis of Data

The present paper describes a house-to-house epidemiological study of conjunctivitis in the rural town of Barwick, Ga., near Thomasville. The field observations were made between May 17 and October 29, 1951. The study population of 486 persons included nearly every family within a mile of the Barwick railroad station and was fairly evenly distributed between white and Negro persons and between the sexes. Children less than 15 years of age included 33 white males, 49 white females, 45 Negro males, and 51 Negro females. The families were first visited in two groups: one group on May 17th and 18th and the other on June 5th and 6th. Thereafter each group was visited alternately at 2-week intervals except for one 3-week interval in October.

During the house-to-house visiting, information on eye symptoms and on cases of sore eyes was elicited for each member of the family. The informant was usually the mother or another woman tending the household. No cultures were taken, but the eyes of every available person were examined for signs of conjunctivitis.

For the analysis of the data from this study, a case of conjunctivitis is defined as an illness which was called conjunctivitis or sore eyes by either the observer or the informant. Ages are fixed at the number of whole years of age at the end of July 1951. This procedure leads to some inaccuracy but most of the observations still fall within the correct year of age. Case

The authors are with the Communicable Disease Center, Public Health Service. Dr. Dow is a biologist at the Logan Field Station Section, Technology Branch, Logan, Utah, and Miss Hines is a nurse epidemiologist with the Leprosy Control Program, assigned to the Louisiana State Department of Health, New Orleans, La.

Balance in Benefits

Resident «—————» Health Department

| | |
|---|---|
| AMA-approved postgraduate training | Stable, well-trained medical staff |
| Increasing responsibility and status | Relief of regular staff (members) |
| Contact with professional colleagues | Improved relations with doctors and hospitals |
| Reasonable salary for family maintenance | Just compensation for service |
| Association with University Medical School | Recruitment and teaching responsibilities met |
| Modest research activity and special projects | Results of research sometimes applicable |

competent advice is no farther away than the telephone. At a time when the resident's convictions concerning his chosen specialty may be conditional, supervision of this nature mitigates against discouraging mistakes without suppressing initiative. As the resident's capabilities become apparent, responsibility can be delegated in areas that will relieve some of the regular staff.

The resident must become a part of his community and win the confidence of his professional colleagues in that community. He is encouraged to join the medical society and other organizations relevant to his position as district health officer. This representation personalizes the health department on a district level and brings its programs closer to the communities for which they are intended.

Our initial stipend is \$500 per month the first year. The resident through his work in clinics, immunization programs, and other activities actually earns his stipend as much as the hospital resident who performs as house physician. Consistent with increasing responsibility and ability, the stipend is raised to \$800 per month the second year.

Each resident is appointed assistant clinical instructor in public health at the University of Washington Medical School. In this capacity he is expected to assist in teaching public health to medical students and to participate in special seminars and courses, all of which help to fix concepts and material in his mind that he has only recently learned himself. If, by precept

or example, a student is encouraged to choose public health as a career, the resident contributes to recruitment of personnel.

Project activity in our residency program has been both diverse and productive. Residents have contributed significantly to the following: civil defense and disaster preparedness program; publication of a public health reference manual for physicians; poliomyelitis survey; poliomyelitis immunization program; district office administration; investigation of a multiple-puncture tuberculin test (Heaf test); medical consultation for State vocational rehabilitation division.

We have been asked whether a physician with public health experience but without formal training should undertake a residency such as ours. We cannot answer this question categorically, for some physicians have been interested in the orientation part of our program. Certainly a new staff member could profit from thorough orientation to our community and the department. However, our program is primarily designed for training the uninitiated physician in the disciplines he will find essential to his pursuit of a career in public health.

¹ Probability of null hypothesis (that no difference exists between the percentages for whites and Negroes).

Since it is often a matter of opinion as to when one case has recovered and another has begun, the number of separate cases is a less objective figure than the number of persons affected by sore eyes. The numbers of whites and Negroes who were affected and the numbers who were not affected at some time in the course of the study can be compared by fourfold analysis. This method shows that the proportion of white children attacked by sore eyes is significantly higher than the proportion of Negro children in the age groups 1–4 and 5–9 years (table 2). When the numbers of male and female children affected and not affected by sore eyes are similarly compared, the results again reflect the case rates, and there is no evidence of a difference in rates between the sexes.

Duration of Illness

The finding of differences in attack rates between the white and Negro children led to a study of other differences in the two groups. Besides 11 cases of conjunctivitis for which total length was not recorded and 7 cases which may or may not have been recovered on the day of the last pertinent interview, there are 46 recovered cases and 60 cases last reported as active. In Negroes, the cases are of longer average duration whether or not they were active at the time of the last interview, and this is true even if cases of 14 or more days' duration are excluded (table 4). Moreover, 16 of the 22 cases reported to have lasted 2 weeks or longer are in Negroes.

That these figures on duration of illness are

more or less typical of the disease in southwest Georgia is indicated by data on sore eyes collected in 1949 and 1950 during case history studies of diarrhea. In this study, several workers making house visits in the same general area conducted interviews at monthly intervals in 10 different communities in Thomas, Brooks, and Colquitt Counties (4). As in the 1951 data, the average duration of all recovered cases of sore eyes was shorter in white persons than in Negroes: 9.6 and 11.0 days, respectively. The average duration of those recovered cases which lasted less than 14 days was also shorter in whites than in Negroes: 5.0 and 6.1 days, respectively. The significance of this racial difference in reported duration of the shorter cases has a probability of less than 0.01 by the *t* test for unpaired data. The essence of the difference in both sets of data seems to lie in the much larger number of white cases said to have lasted 1 or 2 days (table 5). The basis of the difference between races need not be physiological: it may be sociologic, for example: (a) the degree of illness which each group accepts as a case of sore eyes, (b) the medical treatment given to cases by the two groups, (c) personal hygiene, or (d) some aspect of reporting, such as a tendency of white mothers to minimize the length of time their children remain ill.

Table 3. Numbers of persons having indicated number of cases of conjunctivitis per individual, by age and race

| Age (years) | Number of cases | | | | | | | | | |

NOTE: W—White; N—Negro.

attack rates are expressed as the number of cases times 100 per person-periods of experience. (The word "experience," as used here, means the sum of the unit periods of time covered by the interviewing.)

In the 11 rounds of visiting, the study population of 486 persons might have contributed a maximum of 11 times 486, or 5,346, person-periods of experience; 4,062 person-periods, or 76 percent of this maximum, were actually obtained. Fifty-six percent of the total experience was supplemented by physical examination of the eyes, the total number of examinations being 2,275. The number of eye examinations was disproportionately small for the males over 14 years old; and at the opening of the schools in September, there was a very marked drop in the number of eye examinations in the children of ages 5-14 inclusive. With these exceptions, the sampling of the study population was not unbalanced. No denominators have been adjusted to exclude either persons with chronic conjunctivitis or persons who might have acquired immunity to the disease.

Age, Race, and Sex

Preliminary analyses of the data showed no marked difference in conjunctivitis attack rates between male and female persons of all ages or

between white and Negro persons of all ages. It was apparent from the start, however, that the rates were much higher in children. In fact, only 17 of all the 123 cases occurred in the persons over 9 years old who made up 70 percent of the study population.

With respect to age, the rates for white and Negro children are found to differ markedly, yet rates for both races decrease rapidly after an early peak (table 1). In the white group, the highest attack rate occurs in two separate years (ages 2 and 3). In the Negro group, the highest attack rate occurs at age 1.

When the attack rates for white and Negro children are compared by age groups, the rate for children 1-4 years of age is found to be distinctly higher in the white population than in the Negro population (table 2). When the rates for both sexes are compared without separation as to race, the attack rates for males are higher, but only slightly so, for less than 1, 1-4, and 5-9 years.

Of course the attack rates, based on numbers of cases, are strongly influenced by the informant's definition of a case. Different individuals might count as one case, or as two cases, a single infection which had two separate periods when the signs and symptoms were more severe. In the present study as many as five cases have been reported in one individual (table 3).

Table 1. Conjunctivitis case attack rates in southwest Georgia, by age and race, May 17-October 29, 1951

| Age (years) | White | | | | Negro | | | |
|-------------|---------|-------|-------------------------|-------------------|---------|-------|-------------------------|-------------------|
| | Persons | Cases | Experience ¹ | Rate ² | Persons | Cases | Experience ¹ | Rate ² |
| Less than 1 | 7 | 3 | 62 | 4.8 | 13 | 4 | 71 | 5.6 |

| Over 19 | 182 | 5 | 1,647 | .3 | 101 | 7 | 664 | 1.0 |
| Total | 276 | 75 | 2,508 | 3.0 | 210 | 48 | 1,554 | 3.1 |

¹ Person-periods.

² Cases \times 100 per person-periods of experience.

attack rate, which is based on all children of the same age and race. By thus controlling the effect of age, the effect of family size can be evaluated separately. In the white families with 1, 2, or 3 children, the observed cases are somewhat fewer than those calculated from the rate for all families, and the ratio is reversed in families with more than 3 children. In the Negro families, the relative proportions of observed to expected cases are in just the opposite sequence, there being more cases in the smaller families than the data for the whole Negro group would lead one to expect. Statistically, there is no indication that the occurrence of sore eyes differs in families according to their size.

Another approach to the problem of intra-familial spread of conjunctivitis is to study the relative rate of transmission within family groups by computing secondary attack rates. For diseases in which one case confers lasting immunity, the denominator of a secondary attack rate is simply the total number of family members less the number of primary cases. Because a case of sore eyes may not confer immunity for even a single season (note the large number of multiple cases in table 3), the denominator must be corrected to include only the persons actually at risk. The situation is similar to that studied by Badger and associates in an investigation of respiratory illness in Cleveland, Ohio (5, 6). This group calculated secondary attack rates by studying selected units of family experience called episodes. An episode is defined as a period of 10 days which

Table 8. Number of episodes of conjunctivitis in southwest Georgia, grouped by numbers of index and secondary cases, May 17–October 29, 1957

| Number of index cases | Number of secondary cases | | | | Total episodes |
|-----------------------|---------------------------|---|---|---|----------------|
| | 0 | 1 | 2 | 3 | |
| 1..... | 63 | 6 | 1 | 2 | 72 |
| 2..... | 4 | 1 | 0 | 0 | 5 |
| 3..... | 2 | 0 | 0 | 0 | 2 |
| 4..... | 2 | 0 | 0 | 0 | 2 |
| Total episodes..... | 71 | 7 | 1 | 2 | 81 |

(a) follows a period of 10 days without reported illness of the type under study, (b) starts with the day of onset of the index case (or cases), and (c) continues for 9 more days. Index cases are defined as all cases with onset on the first day of an episode.

In applying these definitions to the data on sore eyes, 12 cases were excluded, 3 because they were recurrences of another case in the same episode. Of the remaining 111 cases, only 15 were secondary, and of the 96 index cases, 63 occurred with no other cases in the same episode (table 8). The small number of secondary cases precludes obtaining satisfactory secondary attack rates but does suggest that there is little spread within the family, at least after the first day of an episode. The fact that many families which had not had any previous or recent cases reported multiple cases with the same date of onset might

Table 7. Distribution of cases of conjunctivitis in southwest Georgia,¹ by number of children in family, May 17–October 29, 1951

Table 4. Average duration of cases of conjunctivitis by race, May 17–October 29, 1951¹

| Type of case | White | | Negro | |
|---|-----------------|-------------------------|-----------------|-------------------------|
| | Number of cases | Average duration (days) | Number of cases | Average duration (days) |
| All recovered cases----- | 33 | 2.6 | 13 | 4.9 |
| All active cases----- | 37 | 4.5 | 23 | 18.1 |
| Recovered cases of less than 14 days' duration----- | 32 | 2.3 | 12 | 4.1 |
| Active cases of less than 14 days' duration----- | 32 | 2.1 | 8 | 6.4 |

¹ Excluded are 7 cases which may or may not have been recovered on day of last pertinent interview and 11 cases for which total duration was not recorded.

Some light is shed on the question of reported duration of conjunctivitis by analyzing the records of treatment which were obtained in 1951. There are relatively more cases in the Negro population reported as having received no treatment (10 out of 48 cases) than in the white population (7 out of 74 cases). A greater difference, however, lies in the number of cases whose treatment included an antibiotic or the care of a physician (3 out of 48 in the Negro group, 30 out of 74 in the white group). Re-

Table 5. Duration of recovered cases of conjunctivitis in southwest Georgia, by race, 1949–50 and May 17–October 29, 1951

| Duration (days) | Number of cases | | | |
|-----------------|-----------------|-------|-------------------|-------|
| | 1949–50 | | 1951 ¹ | |
| | White | Negro | White | Negro |
| 1----- | 30 | 3 | 11 | 1 |

| 8–14----- | 145 | 180 | 1 | 0 |
| 15–21----- | 46 | 61 | 0 | 0 |
| 22–31----- | 34 | 22 | 0 | 0 |
| 32–120----- | 26 | 21 | 0 | 0 |
| Total----- | 803 | 631 | 33 | 12 |

¹ For cases for which approximate duration was given, whole days of duration were obtained by taking the first whole number above the mean.

gardless of the efficacy of any medicine used, the Negro population appears to have secured less treatment of an up-to-date nature.

Seasonal Occurrence

Grouped by month of onset, the cases of conjunctivitis in the white population show a small peak in June but are much more frequent in August, September, and October (table 6). The Negro cases have two peaks, one in June and one in October. The monthly attack rates

Table 6. Month of onset of conjunctivitis cases, by race, May 17–October 29, 1951

| Month | White | Negro |
|----------------|-------|-------|
| May----- | 3 | 7 |
| June----- | 10 | 12 |
| July----- | 8 | 5 |
| August----- | 18 | 6 |
| September----- | 15 | 7 |
| October----- | 21 | 11 |
| Total----- | 75 | 48 |

present the same picture, but here, as in the monthly totals, the numbers of cases are too small to justify any interferences.

Spread Within the Family

In spite of strong circumstantial evidence that the eye gnat is a vector of sore eyes, there is no reason to question the importance of transmission of conjunctivitis by contact, especially within the family. Opportunities for the direct transfer of infectious material from one person to another can be assumed to be more frequent between members of a family than between persons in the community as a whole, and, on the basis of this assumption, large families might be expected to have higher attack rates than small ones. For comparison with the number of observed cases of conjunctivitis in families with different numbers of children, the expected number of cases can be computed for children 0–14 years of age (table 7) by adding the number of expected cases for each child in each family. The number of expected cases for each child is the product of the person-periods of experience for each child times the age-specific

eyes than within this group. Palpebral hyperemia and crusts are therefore of dubious use in diagnosis. As a matter of fact, palpebral hyperemia was often difficult to recognize with assurance, and the presence of crusts may be in part related (inversely) to the availability of a water source and the frequency of washing the face.

The use of histories in the diagnosis of sore eyes seems to be justified on the basis of one very characteristic symptom, adherent lids, usually observable only when the individual awakes in the morning and therefore rarely seen by a person doing interviews. This symptom is mentioned in the history of 2 out of every 3 current cases; it is the symptom most frequently reported; it is recorded as a symptom more often than any sign; and finally, it is cited only once in the entire study in a person without reported sore eyes.

Discussion

To consider conservatively the results and possible implications of the present investigation, it is well to review its limitations. In line with the original purpose of investigating possible contacts between persons who had acquired cases of conjunctivitis, the study population was concentrated in one small area. It therefore cannot be considered a satisfactory sample of any larger group, and its comparatively small size is another disadvantage.

The lack of bacteriological culturing, which might seem an insuperable handicap, was unfortunate, but it did not seriously affect the study of illness as distinguished from infection. Actually, illness due to conjunctivitis cannot be measured by routine bacteriological culturing because infection with one or another species of *Haemophilus* (*aegyptius* or *influenzae*) has been found to persist in essentially asymptomatic persons for several months, according to unpublished observations of Dr. Dorland J. Davis.

Another limitation is a deficiency in the information on duration of illness, which resulted from failure to obtain the date of recovery for some cases. Another difficulty is the lack of basic data on immunity and the resulting problem of calculating satisfactory case attack rates.

Because the denominators cannot be corrected to exclude persons who were not at risk, the ratios do not represent an expression of the probability of infection and, accordingly, cannot be compared by means of the usual tests of significance.

In spite of all these drawbacks, several aspects of conjunctivitis observed in this study may well be characteristic of the disease over a much larger area. These findings are all concerned with differences between the white and Negro groups but are not dependent on the fact that the attack rates in the white group are higher than in the Negro group. First, the reported duration of acute cases is much shorter in the white group, and chronic cases (lasting 2 weeks or more) are much more common among the Negroes. Second, the records show that the white population took a more modern and more aggressive attitude toward the treatment of conjunctivitis. Third, in the white population there are more instances of multiple cases occurring in one individual. Fourth, the white age-specific attack rates decline more slowly with increase in age than do the Negro's.

These findings show that any attempt to measure the incidence of conjunctival disease should take into account the racial distribution of the population as well as its composition by age. They also indicate that much work needs to be done on the problem of susceptibility. Future studies of *Haemophilus* conjunctivitis should deal with the immunity conferred by previous cases, both treated and untreated, and should also explore the relation of overt illness to infection. With information on these aspects of the disease, it might be possible to show that, in areas where there are frequent opportunities for infection, the occurrence of new cases is closely related to losses in immunity.

Summary

An epidemiological study of conjunctivitis conducted in a rural town in southwest Georgia was based on interviewing and eye examinations without bacteriological culturing. Cases of conjunctivitis were less frequent and of longer duration in the Negro population than in the white population. There was no distinct

be the result of failure to recognize an initial case, but this is not necessarily so. Sore eyes will incubate in less than 24 hours, at least under artificial conditions (7); therefore, the spread from an original infection might be rapid enough to result in apparently simultaneous cases. Another possible explanation of the numerous cases occurring on the first day of an episode is that they might all be contracted from a source outside the family, perhaps even from eye gnats. If the infections are acquired through intrafamilial contact with an initial case, they are properly considered as secondary. If they are acquired, along with the initial case, from a source outside the family, they are indeed multiple index cases and their origin is a matter of real importance.

Diagnostic Symptoms

Whether or not a person was believed to have conjunctivitis, the record of the interview includes observations on all eye conditions of possible diagnostic value. These are reported as signs if observed during the physical examination, and as symptoms if included in the history. During the field work, bulbar hyperemia and purulent exudate were used to diagnose cases of sore eyes, and in consequence, these

conditions may have been reported more completely than the rest. In other respects as well, the information on signs and symptoms must be interpreted with caution. One reason is that "sore eyes" is so common a disease in southwest Georgia that many informants would take little notice of the exact signs or symptoms in a particular case. Another reason for careful handling of the data is that many cases were very mild. Though provision was made to grade both signs and symptoms in three degrees of intensity—mild, moderate, or severe—"moderate" was used only five times in the records, and "severe" not at all.

Despite the character of the data, it is possible to compare some of the signs and symptoms in persons reported as having conjunctivitis with those in persons not reported as ill (table 9). This comparison shows that two eye conditions, palpebral hyperemia and palpebral crusts, are not reliable in the diagnosis of conjunctivitis. Palpebral hyperemia was found as a sign 50 times in persons believed to have, or to have had, sore eyes and 78 times in persons believed not to have the disease. Palpebral crusts were seen 31 times in persons counted as having or having had sore eyes, and 41 times in persons counted as negative. No other sign, except colds and nasal conditions, was noted more times outside the group affected by sore

Table 9. Frequency of signs and symptoms of conjunctivitis in southwest Georgia, May 17–October 29, 1951

National Academy of Sciences-
National Research Council*

Cancer and Food Additives

IN the development of our knowledge of nutrition, primary emphasis has been given to deficiencies that may occur in our diets and to ways of safeguarding against them. Along with the application of such knowledge a notable reduction in dietary deficiency diseases has occurred. With decreasing need in the United States for emphasis in this direction, more effort has been devoted to the investigation of positive factors in foodstuffs that might be detrimental to health.

A group of conditions broadly termed "degenerative diseases" has assumed major importance as causes of illness and death in recent decades. The causes of these conditions are under intensive investigation, and especial emphasis is being placed on the role of environmental factors.

Causal relationships between environmental factors and human disease have long interested scientists. Indeed, knowledge of such relationships underlies most advances in preventive medicine. It is not surprising, therefore, that investigators at present are trying to determine whether factors in the environment are causally related to the occurrence of cancer in man. As has been true in the study of all diseases whose causes are unknown, the elements of the environment to which man is constantly or repeatedly exposed, for example, the atmosphere, water, and foodstuffs, command the greatest share of attention.

Legitimate Conjecture

Conjecture concerning possible cause and effect relationships is a common and sometimes an effective device in the development of new knowledge concerning disease. Many discussions concerning the possible relation of chem-

icals which may occur in foods to the occurrence of cancer in man have been held at scientific meetings, and reports of these have recently appeared in scientific publications. Scientists involved in discussions of food additives and cancer recognize the conjectures as such, and ascribe importance to them only insofar as they may stimulate the kind of inquiries which will help advance knowledge. When the scientific discussions, either written or spoken, have been reported through the press and other news media for public information, however, the conjectural nature of the scientists' discussions has frequently been forgotten, misconstrued, or poorly stated. This has contributed to the present apprehension among consumers over the safety of the food supply, and to the concern among food manufacturers over the possible loss of consumer confidence.

In view of these circumstances, it is desirable that a statement be made clarifying for the public the present state of knowledge about the relation between food additives and occurrence of cancer in man.

Known Facts

What is known concerning a definite relationship between ingestion of a substance and the subsequent development of cancer in man? Accidental repeated ingestion of radium paint or the use of so-called radium water has been followed by the development of cancer of the bone. The ingestion of certain aromatic amines, such as *b*-naphthylamine or 4-amino-diphenyl, through industrial exposure has been associated with the occurrence of cancer of the bladder. Epidemiological evidence indicates that a prolonged intake of sufficient arsenic may result in development of cancer of the skin.

difference in incidence with respect to sex, but the incidence by age group was highest in children 1-4 years of age, decreasing rapidly in the age groups 5-9 and 10-14 years. This decline, which was more rapid in the Negro group, is discussed in addition to other racial differences. A study of intrafamilial spread showed that multiple index cases are very frequent and secondary cases relatively scarce. Palpebral hyperemia and palpebral crusts were of little or no use in visual diagnosis, but adherent lids, reported as a symptom by informants, were strongly indicative of conjunctivitis.

Departmental Announcements

John Alanson Perkins, Ph.D., was sworn in as Under Secretary of Health, Education, and Welfare on April 5, 1937, to succeed Dr. Herold C. Hunt. Dr. Perkins has been president of the University of Delaware since 1950.

He was president of the American Society of Public Administration in 1953 and since that date has been a member of the Executive Board of the United Nations Educational, Scientific, and Cultural Organization. He has also served as a member of the Social Science Research Council's Committee on Organization for Research. He served as secretary to the late Senator Arthur H. Vandenberg and has been a teacher of political science both at his alma mater, the University of Michigan, and at the University of Rochester.

Dr. Perkins became budget director of the State of Michigan in 1946 and in 1948 was appointed controller of the department of administration. He has served as a member of the State planning commission and of the Educational Policies Commission of Michigan.

Edward Foss Wilson, a Princeton graduate, was sworn in as Assistant Secretary of Health, Education, and Welfare (Federal-State relations) April 5. Former president and chairman of the board of Wilson & Co., Inc., Chicago, he has been active in civic affairs and in various voluntary organizations.

Mr. Wilson has been director of the Presbyterian-St. Luke's Hospital for the past 20 years and of the Illinois Division of the American Cancer Society for the past 9 years. He is a member of the Council on Medicine and Biology of the University of Chicago.

For his many services in the field of health and welfare, a citizen fellowship was conferred upon him by the Fellows of the Institute of Medicine in Chicago on December 4, 1956.

Katherine Brownell Oettinger has been appointed chief of the Children's Bureau to succeed Dr. Martha M. Elliot, who recently resigned to become professor of public health at the Harvard School of Public Health.

Prior to her previous post as dean of the Boston University School of Social Work, which she assumed in 1954, Dean Oettinger was a division chief in the bureau of mental health, Pennsylvania Department of Welfare. Before that she was engaged in psychiatric social work at a children's treatment center in Scranton, Pa., and in child guidance and family welfare work in New York City.

Dean Oettinger has been on the board of directors of the Massachusetts Association for Mental Health and on the Advisory Committees of the Child Guidance Foundation and the Massachusetts Society for Crippled Children. She is currently a member of a number of organizations concerned with social work.

Ethiopian Assignment

IN August 1954 the Ethiopian-American Public Health Joint Fund assumed responsibility for operating the Haile Selassie I Hospital in Gondar, Ethiopia. The fund's mission was the transformation of this institution of some 100 beds into a demonstration hospital and medical center where technical personnel would be trained. My main responsibility was to set up the laboratory. Primarily, it was to be used for training laboratory technicians, but it would also be available for use as a hospital service. My assignment also included teaching all the biological sciences and laboratory methods in the Public Health College and Training Center in Gondar.

I arrived in Gondar with my family on June 4, after 2 months at headquarters in Addis Ababa. Gondar is a town with a population of about 22,000 in northwestern Ethiopia. The great and pardonable curiosity of its populace was entirely reciprocated by my family. Because of our official status, a detail of rifle-carrying police was assigned to guard our house day and night, but at our request it was withdrawn.

Before the formal transfer of the hospital to the fund, we visited the grounds to become familiar with conditions and personnel.

Laboratory personnel consisted of 1 technician and 1 apprentice on detail for training from the nearby provincial army post. The

Dr. Arthur H. Webb writes an account of his assignment in Ethiopia from April 9, 1954, to April 28, 1956. His duties involved setting up a laboratory in Gondar and teaching biological sciences and laboratory methods in a college in that town. During his tour of duty Dr. Webb was on leave from the post of assistant professor of bacteriology at the Howard University Medical School, Washington, D. C., to which he returned after completion of his assignment.

laboratory equipment was a microscope, a table, some stains, and miscellaneous broken pieces of glassware. There was no laboratory budget; infrequent doles of alcohol were wheedled from the pharmacy, and Giemsa stain was purchased from time to time from personal funds of clinical staff members. Conferences with the laboratory technician, through an interpreter, revealed that he was performing a surprising range of simple laboratory procedures with practically no equipment, and that he was discouraged.

This technician, Ato Araya Guhley, had been presumably well trained at the Pasteur Institute in Addis Ababa, but owing to lack of working facilities his knowledge had deteriorated during the 8 years spent at the Gondar Hospital. He was at this time performing, more or less creditably, fecal examinations, blood counts, examinations for malarial parasites and relapsing fever, a simple urinalysis, and stains for tuberculosis, gonorrhea, and leprosy. He appeared to be sincerely interested in laboratory analysis and was enthusiastic about relearning things he had forgotten and in acquiring new skills.

Therefore, the first project was to stimulate Ato Araya with descriptions of projected development and to "sharpen" his performance. His response was satisfactory, and it was then possible to move on to a second phase of laboratory development.

Although the laboratory building was not completed, and the equipment not yet delivered, we decided to conduct a training experiment. A particularly alert youngster, a lad of 17 with 7 years schooling devoid of science instruction, was selected from a group of day laborers and put into the laboratory as a trainee. We wished to see if unusual pedagogical techniques were necessary.

The lad, Asfan Makonnen, turned out to be

Do these materials occur in the food supply of the United States? Arsenic is the only one. It may occur in some foods in extremely small concentrations as a pesticide residue and is normally present in certain foodstuffs which have received no pesticide treatment. Insofar as is known, there is no danger from the amount of arsenic likely to be consumed from these sources under ordinary conditions.

If this were all of the story, probably no public apprehension would have arisen.

Experimental Animal vs. Human Cancer

Investigators studying cancer have induced the development of tumors in experimental animals by purposely exposing them to a number and variety of chemicals. Such experimental cancer may be produced in animals by giving the agent by injection, by skin application, or orally. From this evidence and knowledge of how man may be like or different from the experimental animal in the metabolism, excretion, or storage of a particular chemical, the scientist can form a hypothesis as to how man might react to the ingestion of the chemical.

In this respect, the conservative position would demand that substances that produce cancer in experimental animals should be excluded from human foods as a precautionary measure, even though it is known that a substance carcinogenic in one species is not necessarily carcinogenic in others.

Knowledge about possible cancer-causing agents in foods is, in general, at the point that studies are being devised and undertaken to test such possible relationships. This research is, by its very nature, expensive and time consuming. Years of study will be required to build definitive knowledge concerning all causes of cancer. There is a need to continue and expand present efforts to identify any relationships which may exist between environmental factors and the occurrence of cancer in man. Measures taken to safeguard the food supply can be only as effective as our state of knowledge permits. Government agencies, the food industry, and bodies such as the National Research Council are working together to facilitate the development of this knowledge and its effective application as soon as the information becomes available.

Pearl McIver Retires From PHS

Pearl McIver, R.N., B.S., M.A., will retire from the Public Health Service in June 1957 to become the executive director of the American Journal of Nursing Company. At present she is chief of Public Health Nursing Services, Division of General Health Services.

A pioneer and recognized leader in her field, Miss McIver was the first public health nurse to enter the Public Health Service. After serving 10 years as director of public health nursing with the Missouri State Board of Health, she was appointed in 1933 as a public health nursing analyst in the Division of Scientific Research. In 1935 she became chief of the Service's Division of Public Health Nursing, a position she held for 22 years.

A special consultant to the World Health Organization for technical discussions on nursing at the 1956 World Health Assembly, Miss McIver was named during the same year

"Public Health Nurse of the Year" by the American Nurses Association. She was one of the recipients of the Lasker Group Award of 1955, and in 1951 received the Outstanding Achievement Award of the University of Minnesota.

Among the posts Miss McIver has held in a number of organizations were those of vice president of the American Public Health Association, president of the American Nurses Association, and chairman of the International Council of Nurses Committee on Constitution and Bylaws.

On Miss McIver's retirement, Margaret G. Arnstein, R.N., M.P.H., chief of the Division of Nursing Resources, will become chief of Public Health Nursing Services. Scheduled to assume the duties of Miss Arnstein is Apollonia O. Adams, M.A., now deputy chief of nursing resources.

a little English and were enthusiastic and faithful. Alemu, an amputee who had been dependent on the hospital social service department, was able to marry and establish his own home. Tashoma was like a proud housewife in his zeal to keep the building clean. Beyenne had learned to make bacteriological culture media and was now training as a laboratory technician. But the washroom had not always been so harmonious. The men had had no experience with laboratory glassware, and breakage was exuberant. Gradually, it came to be no more than one would expect in an operation of this size.

In October 1954 the teaching program of the health center started. Twenty-four young men of a broad variety of educational backgrounds were received. Some were proficient in English; some barely understood it. The course in biology cum physiology that I taught 4 hours a week for 15 weeks was about the hardest work I have ever done. Not only did I teach biology, I taught English as well, defining every word and writing it on the board.

Next were two trimesters of formal instruction and laboratory practice in the usual clinical diagnostic procedures, with emphasis on simple techniques considered most useful and reliable under field conditions.

When the second school year opened in October 1955, a second class of 34 health officer students and a first class of 20 community nurse students were admitted. The staff had decided to give the students short basic survey courses in biology, mathematics, physics, chemistry, and other sciences so that all students could be presumed to have had certain standard basic information.

I conducted a basic biology course of 16 lectures and demonstrations, designed as a background for understanding the functioning of the living organism. At the same time, second-year health officer students were assigned to the laboratory on rotation and, working under supervision of laboratory personnel, helped perform the laboratory routine.

During the second trimester of this school year, this laboratory practice was continued, and courses in microbiology were given to first-year male students and to community nurses.

The laboratory teaching of relatively inexperienced students is a process calculated to turn hair gray. The burden of individual instruction was partially solved by drafting three laboratory workers into the teaching laboratory as "graduate assistants." Seeing that students followed directions demanded constant vigilance.

Despite these difficulties, as well as chronic shortages of materials and lack of sufficient microscopes, instruction was given in microscopic fecal examination for parasites, hematology, the Kahn test for syphilis, and microscopic bacteriology. The second-year health officers made some small start in clinical chemistry as well.

There had always been at the Gondar hospital an informal training program for Imperial Army personnel. The army post commander, who is highly popular with the international personnel readily agreed to establish a laboratory to utilize the experience of soldier trainees, and a laboratory was set up with supplies and materials "loaned" from our stock on a returnable "if" and "when" basis. This installation served an army community of about 3,000 persons, did 10 to 15 tests a day, and sent us material for those procedures which it could not carry out. We continued to supply the installation.

Early in 1956 we were approached by the director of medical training, Ethiopian Ministry of Public Health, who asked us to share a training program with the Pasteur Institute of Addis Ababa. The arrangement provided for 6 months of didactic instruction at Pasteur Institute and then for 6 months of practical training in our laboratories.

In 1956 the laboratory employed 10 persons and had 5 army and Pasteur Institute trainees. For the first 25 days of that month, we registered 953 people for whom we performed 980 tests.

A fairly trustworthy service in hematology was offered, and our urinalysis and fecal examinations were good. We did only the Kahn test for syphilis, but the serologist was enthusiastic and ready to learn other tests. His performance could be depended upon. Bacteriology and chemistry were slow in development, I suspect because they require more judgment

an unusually fortunate selection. After a mere 20 months in the laboratory, he carried most inventory details in his head, prepared solutions and reagents, performed all the technical operations, and helped train new personnel. He organized projects and prepared data for reports; it was only necessary to explain carefully what was wanted, answer a few questions, and then leave it to Asfau. This was a prime example of an individual who needed only a chance. There is no reason to assume that he is remarkably different from other bright boys; he merely points up the unexplored and undeveloped potential of his fellows. Rapport was facilitated not only by his high degree of innate ability, but also by his unusual proficiency in the English language.

Real laboratory work began in December 1954 with delivery of the laboratory supplies and equipment. These were packed in 34 boxes on two huge trucks which came approximately 400 miles over rough, wornout mountain roads from the port of Massawa, Eritrea, to Gondar, at an altitude of 6,700 feet. The road rises to 12,000 feet at points. The crew assembled to unload the boxes had had apparently little experience with packages of that size and weight. They were willing workers, but the fact that one box exceeded one man's strength was something new; this is an area where the standard load is a donkey load or head load. With much confusion, shouting, and effort, boxes started to move. The scene remains vivid: 500-pound boxes of glassware dropped 6 feet from truck bed to hard-packed earth . . . 12 men maneuvering a 600-pound case to place it carefully on the back of one man . . . watching that one man literally sink into the earth beneath his load . . . trying to live through the conference that ensued before the box was finally lifted off the man . . . wondering whether lives would be lost . . . then, unpacking . . . the gay and vigorous hacking with axes and sledge-hammers at cases that contained precision instruments . . . one man inside a large box pitching out small packages.

Miraculously, out of approximately a quarter million separate pieces not a single item broke. Inventorying was smooth but slow because the new laboratory trainees, previously

selected and called to duty at this time, were unfamiliar with most items.

Two weeks after delivery of the equipment, training proceeded in earnest. Ato Araya, the senior technician, continued to be responsible for hospital work, while Asfau, the first trainee, assisted with new men. The first project was urinalysis; this was done on a somewhat mechanical basis without reference to theory. After about a month of this, when hands and eyes became familiar with colors and manipulations, the student health officers attending the Public Health College and Training Center entered laboratory training. Through the lectures for college students, the laboratory trainees learned the significance and theory of the manipulations they had already learned mechanically. Then too, with their new mechanical skills, they were able to give individual instruction to the professional students. Laboratory trainees and health officer students took the same examinations. As expected, trainees did better in practical work, and students excelled in theory.

In a relatively short time it was possible to build up a staff with fair proficiency in hematology, examination of feces, urinalysis, detection of blood parasites commonly found here, simple microscopic bacteriology, and syphilis serology.

The selection of personnel, ordinarily a major program, was simplified by the large number of applicants. Men chosen sometimes "on hunch" have on the whole worked remarkably well. Alazar was developing proficiency as a bacteriologist; Mammo's Kahn test was to be depended upon; and Mellise would some day be a competent hematologist. Gebre Sellassie and Asfau worked well in all fields. There were as yet no specialists; all had to serve where the work was heaviest. But each was allowed a measure of responsibility in one field; for example, all Kahn testing had to be done under Mammo's supervision.

While technical divisions of the laboratory were developing, the service branches were working, also. Since the trainees who spoke English were schoolboys without dependents, we staffed the washroom with mature men with families. These three were beginning to speak

Venereal Disease Contacts of Servicemen in Massachusetts, 1949-55

By NICHOLAS J. FIUMARA, M.D., M.P.H.

IN PREVIOUS publications I have outlined the philosophy and principles which guide the civilian venereal disease control officer in his relations with the military venereal disease problem (1-4). Briefly summarized, the civilian control officer is aware of the fact that the control of venereal diseases among military personnel is a joint function of military and civilian authorities. A military program aimed at the prevention and control of venereal diseases will be effective only to the degree of joint participation by the military and civilian partners. Each group must assume responsibility in certain areas, but the work of one must complement the efforts of the other. Failure of one partner to carry out his assigned tasks or failure to integrate military and civilian responsibility will result in weakening not only of the military venereal disease control program but the civilian program as well. It is my purpose to describe our experiences over the past 7 years in locating and examining venereal disease contacts who were named by infected military personnel and who could be found in Massachusetts.

Contact investigation begins long before civilian authorities receive contact reports. Actually, contact investigation in the armed

forces begins at the military installation with the infected serviceman who is being interviewed. It is the experience of venereal disease control officers that results of contact investigations vary, other factors being equal, with the adequacy or inadequacy of the interview (5, 6).

Once the interview is completed, the information obtained is transcribed on the prescribed epidemiological report form (PHS 1421-VD-REV. 3-53) and sent to the appropriate civilian health authorities. The essential contact information should be sent as speedily as possible. When feasible, telephone reports should be encouraged, and telegrams should be sent when out-of-state contact data are obtained. However, the prescribed report form must be completed and should be in the mail within 24 hours of the telephonic or telegraphic reports.

Who are the men in the armed services who contracted venereal disease during the last 7 years and named Massachusetts as "the place where their contact could most likely be found"? What is known about these men and their female sex partners? What were the results of our investigation? These data will be the subject of this report.

During 1949-55, 4,675 men in the armed services contracted venereal disease and named Massachusetts either as the place of encounter or exposure, or both. Of these men, 4,297 (91.9 percent) had gonorrhea, 269 (5.8 percent) had syphilis, and 109 (2.3 percent) had one of the minor venereal diseases. The number of infected military personnel reported in any one year fluctuated more or less according to the total strength of the armed forces during that year. Thus, with the increase in military

Dr. Fiumara is director of the division of venereal diseases, Massachusetts Department of Public Health, and lecturer in dermatology and syphilology at Tufts University School of Medicine and Boston University School of Medicine, Boston, Mass. This paper was presented at the First International Symposium on Venereal Diseases and the Treponematoses, Washington, D. C., May 31, 1956.

than the other procedures. Bacteriology was especially delayed because of the fluctuation in incubator temperature; nights were quite cool, and current was off entirely from about midnight to 9:30 a. m.

Therefore, although some of the projected services of the laboratory were not yet fully developed, some phases of the work were far enough along so that some crude figures could be analyzed. Some 4,000 stool examinations gave a positive figure of 74.4 percent. However, these were not general survey figures; they represent only persons who presented themselves for examination. Parasites found most often were *Ascaris* (30.2 percent), *Trichuris* (13.6 percent), and *Endamoeba histolytica* (34.8 percent).

A very low finding of 1.2 percent for ova of *Taenia saginata* is reported, although a high incidence of *Taenia* infection in humans was presumed. Beef is eaten raw on ceremonial and other occasions, and *Taenia saginata* is considered somewhat of a national pest. It is to be expected that beef animals are rather heavily

infected. Indeed, purgation in the hospital sometimes produced a yard or two of tapeworm, but *Taenia* eggs were rarely found in stool examinations conducted by fairly competent people. There is, however, a universal practice of taking periodically a local vermifuge, Kosso, which must move out the mature egg-producing sections of the worm, leaving the upper portions intact. There is also the possibility, since gravid proglottids detach themselves and actively pass the anal sphincter to expel their ova on the outside, that the feces were not the place to look for them. If Kosso is actually effective against the large flat tapeworm, it must have practically no effect on the large round *Ascaris lumbricoides*, which showed up in almost every positive stool.

These laboratories were staffed entirely by Ethiopian nationals. One may feel competent to predict that perhaps after some are sent away for further training Bagemder Province will have a clinical and public health laboratory that will compare favorably with any similar institution in that part of the world.

Abstracts of Soviet Medical Literature

The National Institutes of Health of the Public Health Service has completed arrangements with the Excerpta Medica Foundation of New York City for the translation and publication of abstracts representing Soviet contributions to medical research. The plan calls for broad coverage of the Soviet medical sciences. The collected papers of the institutes located in various cities throughout the U.S.S.R. as well as the professional journal literature will be covered.

Soviet specialists will contribute abstracts to Excerpta Medica, Amsterdam. The abstracts will be edited by a permanent editorial committee of 30 Soviet scientists appointed by the Excerpta Medica Foundation in cooperation with the presidium of the Academy of Medical Sciences, U.S.S.R., and will be supplemented by verbatim translations of published abstracts of Soviet literature. The whole work will be under the editorial supervision of Excerpta Medica's own specialists. The resulting abstracts, published under the title of "Abstracts of Soviet Medicine," will appear throughout 1957 in two separate series: Part A, Basic Medical Sciences, and Part B, Clinical Medicine.

personnel in 1951 and 1952 during the Korean conflict, reported military cases increased (fig. 1). As the total military strength began to decrease in 1953 and the ensuing years, reported cases of venereal disease decreased. Military cases constituted about 20 percent of the total reported venereal disease morbidity in Massachusetts.

Data on marital and racial status of military venereal disease patients have been kept only since 1951. About 62 percent of the military personnel were white; 38 percent were Negro. About two-thirds of the men were single; about 13 percent were married (table 1). These same proportions held roughly for both whites and Negroes. The widowed, divorced, and sep-

arated contributed slightly more than 2 percent of the series. The marital status of 19 percent of the military patients was not recorded. There was no significant change from year to year in the proportion of single, married, and widowed, divorced, and separated men or of their racial status (fig. 2).

The average age of the military personnel infected with venereal disease over these 7 years was 23.3 years and the average age of their contacts, 24.3 years (table 2). The mean age of both military patients and their contacts has not changed during the past 7 years in spite of the expansion of the armed forces.

However, when military patients are analyzed by ages from 18 to 29 years, inclusive, an interesting trend is observed. In general, the

percent of the military patients stated that contacts were found through their own efforts. Pandering was mentioned in less than 1 percent of the cases, thus indicating indirectly the absence of active, widespread commercialized prostitution (table 4).

Where did the encounter and exposure take place? About 63 percent of the female contacts were said to have been met in a bar. Next in order of frequency was the contact's home which was mentioned by about 12 percent of the servicemen interviewed (table 5). Slightly more than one-third of the exposures for military patients took place in a home, about one-fourth in a hotel, and about one-fifth in an automobile (table 6).

What type of contact information did the interviewer obtain and what were the results of the investigation of these contacts? Complete information was available on 26.8 percent of the 5,148 contacts of military patients sent to us for investigation. With complete information, 85.9 percent of the contacts were found and examined, whereas with incomplete information only 47.6 percent of the contacts were located. Contact information is considered to be complete if there is furnished the contact's complete name and address, her first and last name and telephone number, her first name and telephone number, her complete name and place of employment, or her complete name without the address if it is accompanied with the name

years or older, he would most likely date girls one or more years younger than himself (fig. 3).

During the past 7 years 5,148 girls were named as contacts of the 4,675 infected servicemen, a patient-contact ratio of 1 to 1.1. What was the relationship of the female contacts to the military patients? Most of the girls (71.7 percent) were reported to be pickups, and 19.1 percent were said to be "friends." This word is quoted because in most instances the serviceman did not know his friend's name. Therefore, it is our opinion that about two-thirds or more of these so-called friends could be classified as pickups. Prostitutes were named in 6.4 percent of the total series, and homosexuals were reported in 14 instances (0.3 percent). Thus, as can be seen in table 3, our problem in Massachusetts, as in most areas of the country, centers about the pickup rather than about the professional prostitute. The same types of individuals were reported each year in approximately the same proportion.

How did the serviceman meet the girl? How were the female contacts found? About 96

military cases. The bars are the focal point for most pickups. The home, hotel, and automobile, in that descending order of frequency, are the most common places of exposure.

The results of investigation of contacts depend to a great extent on the type of information supplied by the interviewer. When contact information was adequate, more than 85 percent of the contacts were found and examined, but with incomplete contact data, only about 48 percent were located. The overall result for the past 7 years was that 58 percent of the contacts reported were found and examined. This experience emphasizes the need for concentrating on better and more satisfactory contact interviewing and for devising more efficient methods of venereal disease control.

John F. Mahoney, 1889-1957

Dr. John F. Mahoney, who developed penicillin as a cure for syphilis, died February 23, 1957. At the time of his death, Dr. Mahoney was director of the bureau of laboratories of the New York City Health Department; he was health commissioner

of that city from 1949 to 1954.

Dr. Mahoney was a graduate of the Marquette University School of Medicine. He was commissioned as a medical officer in the Public Health Service in 1917, and in 1925, served as public health adviser to the U. S. Foreign Service. During this assignment in Haiti, Ireland, England, and Germany, he studied methods used in foreign clinics for the control of syphilis.

In 1929, he became director of the Venereal Disease Research Laboratory of the Public Health Service at Stapleton, N. Y., a position he held for 20 years. It was in this post that

he discovered that syphilis could be cured with penicillin.

Dr. Mahoney won the Lasker Award of the American Public Health Association in 1946. The accompanying citation read in part: "The general use of your discovery during World War II helped bring about among our armed forces notable reductions in amount of time lost from duty because of venereal disease; in the same period there was no increase in syphilis among the American civilian population."

Dr. Mahoney served as chairman of the Committee of Experts on the Venereal Diseases, World Health Organization, and chairman of the Committee for Standardization of Serologic Tests for Syphilis, American Public Health Association.

The author of more than 50 papers and articles in medical, scientific, and professional journals, he served as associate professor in clinical syphilology at New York University School of Medicine, and in dermatology at Columbia University School of Medicine.

and address of a friend or associate. Information is classified as complete or incomplete on receipt of the contact data at our central office. In many instances, on investigation it is found that the data furnished by the patient are erroneous or false. In spite of this, however, for statistical purposes the information is still coded as complete. Thus, the staff was able to find about 58 percent of the named contacts of military patients (table 7, fig. 4).

Summary

Between 1949 and 1955 there were 4,675 armed forces personnel who contracted venereal disease and named Massachusetts as the place of encounter or exposure, or both. About

92 percent of the cases reported were gonorrhea. Approximately 62 percent of the military personnel were white and 38 percent were Negro. About two-thirds of the men were single, and 13 percent were married. These same proportions held roughly for both whites and Negroes. The widowed, divorced, and separated contributed slightly more than 2 percent of the series. In spite of an increase in the armed forces, the average age of the infected men and their contacts has not changed for the past 7 years. It was 23.3 years for the men and 24.3 years for the contacts. The venereal disease control problem in Massachusetts centers about the pickup: the prostitute was named in only 6.4 percent of the

Figure 4. Results of investigation of contacts of military venereal disease patients, Massachusetts, 1949-55.

and 1947. By 1949 and 1950 a small number of places, convinced of the benefits to be derived from fluoridation, instituted the measure as a regular practice. Late in 1950 published reports confirmed the anticipated reduced incidence of dental decay resulting from the addition of fluoride to drinking water, and national professional organizations endorsed the procedure. As a result, 109 communities in 1951 and 182 in 1952 decided to bring this health measure to their people, and the trend in reduction of tooth decay by an observed two-thirds was well under way.

As adoption of the procedure gathered momentum, the number of people drinking fluoridated water increased from about 1.6 million in 1950 to 5 million in 1951, 13.6 million in 1952, 17 million in 1953, 21 million in 1954, 24.8 million in 1955, and finally reached 31.4 million last year (fig. 1).

During the entire 12-year period, 80 communities, which at one time served fluoridated water to 1,900,000 people, discontinued the procedure. Of these, 10 communities, serving 223,000 people, reinstated the practice (table 2).

According to the 1950 Census of Population,

¹ Most recently available population figures were used regardless of the year that fluoridation was instituted.

This second summary of the status of fluoridation includes the number of communities adding fluorides to their water supplies, the number of water supply systems, the population served, and the percentage of towns in each population category using this public health measure.

Status of Controlled Fluoridation in the United States, 1945-56

DURING 1956 fluoride was added for the first time to the drinking water of more than 6,500,000 people (table 1). This is nearly twice the number of people who started drinking fluoridated water in 1955. The 1956 increase was exceeded only in 1952 when 8,600,000 people started drinking fluoridated water.

In 1956, 213 communities started fluoridating their drinking water, a larger number than in each of the preceding 2 years. The number of water supply systems which these communities represent was slightly fewer than the number starting fluoridation in 1955 (92 compared with 96).

During the year, 12 water supply systems, representing 16 communities and serving a population of 185,000, discontinued fluoridation. Four water supply systems, representing an equal number of communities and serving 38,000 people, reinstituted the practice after discontinuance.

Although the annual rate of increase in the number of water supplies instituting fluoridation remained about the same during the last 3 years, there was a decline in the rate at which water supplies discontinued fluoridation. In 1954, 20 systems discontinued this public health measure. In 1956, 12 water systems stopped fluoridating. Two systems reinstituted fluoridation in 1954, four in 1956.

By the end of 1956 nearly 1,500 communities with 31,500,000 people fluoridated their water. It has been estimated that about 110,000,000 people in the United States are served by community water supply systems. At the present time about 1 in every 4 of these people are drinking water with adjusted fluoride content. It seems apparent that the number of people using water with a controlled fluoride content will continue to increase at a substantial rate.

The year 1956 was the 12th year in which the practice of adding fluoride to the drinking water in optimal amounts has been practiced as a caries control measure. The procedure was started in a few study communities in 1945. More study communities were added in 1946

Figure 1. Population drinking water with adjusted fluoride content, 1949-56.

*Prepared by the Division of Dental Public Health,
Bureau of State Services, Public Health Service.*

Figure 2. Percentage of communities fluoridating their water supplies, by size, December 31, 1956.

using fluoridation increased from 12 to 15 percent, and the percentage of those under 2,500 increased from 4 to 5.

Water supplies in 85 percent of all communities fluoridating are operated under public ownership. The proportion is similar among large and small cities.

How the institution of fluoridation was authorized is a subject of considerable interest. In nearly 85 percent of the communities the governing body alone constituted the authority for

the action. In 5 percent, the authority was referendum; and in 4 percent of communities fluoridating, the utilities commission made the decision. It is interesting to note that in 91

there were 18,548 communities in urban and rural territory in the United States. Table 3 presents a comparison of these communities, by size group, with the numbers of places using controlled fluoridation. Two of the five communities of over 1,000,000 population are now fluoridating their drinking water as are 8 of the 13 communities of 500,000 to 1,000,000 population. Thus, 55 percent of the largest cities in the country have adopted the measure. From 25 to 30 percent of places ranging in size from 10,000 to 500,000, and 15 percent of the

places from 2,500 to 10,000 population are now fluoridating. Of the 14,000 places of less than 2,500 population, only 5 percent are adding fluoride. Figure 2 shows the number of communities, by size, that have adopted the fluoridation procedure.

During 1956 the proportion of cities of 500,000 population and more that were fluoridating increased from 45 to 55 percent. Those with a population of from 10,000 to 500,000 people increased from 24 to 28 percent. The number of places from 2,500 to 10,000 in population

National Research Council*

Supplementation of Dietary Proteins With Amino Acids

During the past few years the commercial production of a number of amino acids has progressed to the point where the cost is low enough to permit considering them for food fortification. Methionine is being added on an increasing scale to a greater variety of animal feeds. This practice has been shown to improve the feed with a consequent economic gain to the farmer.

Although there are a few reports on the benefits resulting from the supplementation of infant formulas with lysine (1), there is some question about the interpretation of the observation (2). Apart from the preceding consideration, there is a considerable amount of work with animals which indicates that the addition of an amino acid to a poor diet may sometimes aggravate the protein deficiency. These disturbances may result not only in poorer growth but also in the development of abnormalities such as fatty livers (3, 4).

The Food and Nutrition Board of the National Research Council at a recent meeting issued the following statement.

The possibility of correcting a dietary deficiency of an amino acid by supplementation with that acid is an attractive one. There are, however, several guiding principles which should be emphasized at this time.

Attention is called to the Statement of General Policy in Regard to the Addition of Specific Nutrients to Foods, issued by the Food and Nutrition Board in November 1953:

"With carefully defined limitations, the principle of the addition of specific nutrients to certain staple foods is endorsed for the purpose of maintaining good nutrition as well as for correcting deficiencies in the diets of the general population or of significant segments of the population. The requirements for endorsement of the addition of a particular nutrient to a particular food include (a) clear indications

of probable advantage from increased intake of the nutrient, (b) assurance that the food item concerned would be an effective vehicle of distribution for the nutrient to be added, and (c) evidence that such addition would not be prejudicial to the achievement of a diet good in other respects."

Some 25 amino acids are needed for the formation of the various cellular proteins of the body and for other special metabolic functions. Most of these acids can be synthesized by the body, if dietary protein intake is adequate. There are, however, at least eight which must be supplied daily by the protein in the diet in proportions and amounts to meet the requirements of metabolism. Any dietary protein which is relatively deficient in one or more of these essential amino acids has a reduced nutri-

percent of places of 25,000 and over in population, the procedure was authorized by the governing body. The smaller places resorted to referendum or utilities commission action with a little greater frequency—the largest percentage (6 percent) being observed in communities ranging from 10,000 to 25,000 in size. Table 4 shows findings on ownership and authorization.

Today, only 8 of the 18 cities in the country with over 500,000 population are not fluoridating. It is anticipated that most of these eight cities will institute fluoridation within the next

several years. After that occurs the rate of increase in the number of people drinking fluoridated water will depend largely upon the rate of adoption in cities of between 10,000 and 500,000. The lag in the smaller centers may also be overcome during the next several years because of the greatly reduced costs that are now possible, the present availability of simplified and accurate techniques for determining the fluoride content of water supplies, and the growing public acceptance of the measure throughout the country.

Employment After Forty

In a move to reduce enforced idleness, at the root of many difficulties besetting older people, New York State has raised to 38 the number of "older worker" counselors in the State Labor Department's employment service now serving in 15 cities.

These specialists were able in 1956 to find jobs for 4,100 of the 11,000 job seekers over 45 years old who had found their age an insuperable stumbling block in the hunt for work and accordingly had suffered loss of confidence. With the help of the counselors, they were accepted as teachers, purchasing agents, methods engineering consultants, organ makers, foremen, construction workers, bookkeepers, and for a wide variety of other positions.

Supplementing the work of these specialists, State employment offices in all localities emphasize placement of all older workers including those with special problems not related to age. A quarter of a million jobs, better than 1 out of every 4 filled by the employment service in 1956, went to persons over 45.

In part this indicates a generally tightening

labor market, but it also reflects efforts to persuade employers to abandon arbitrary age restrictions. In two cities, Newburgh and White Plains, the employment service found itself with more employer orders for mature workers than it could fill, until local newspapers helped encourage applications from older men and women who had thought that they would never find work again.

The professional office of the employment service in New York City, reporting 40 "older worker" placements in the first month after intensive efforts began, is one of the many offices to note changing and cooperative employer attitudes. Surprise has been expressed by employers at the variety and level of skill in the older group. This office reports that there is a new emphasis on qualifications rather than age and adds that these older workers have been placed in their own fields at their own level, an encouraging improvement over the stopgap type of job that they have been forced to take until recently.

All of us have a responsibility for helping the migrant farm worker and his family share in community services, including health services (see paper on pages 471-477).

tive efficiency. Emphasis is placed, therefore, upon the development of an adequate pattern of essential amino acids in the diet as well as upon the maintenance of an adequate protein intake. Although reasonable estimates can be made of the amino acid mixture which appears "ideal," the limits through which the pattern may vary and still be considered adequate are as yet unknown. Similarly, the definition of the amounts of protein of varying amino acid composition which are required for good nutrition under different physiological states requires further study.

There is reason for believing that nutritive requirements in disease may differ considerably from those in health. An amino acid pattern that is optimum for health and normal growth may require modification in pathological states in which the metabolism of one or another amino acid may be adversely affected. The study of amino acid metabolism in disease and the determination of desirable amino acid patterns in pathological states seem to be matters of great importance which may reveal particular needs for supplementation with specific amino acids or for the reduction of the intake of particular amino acids in the diet.

The imbalance of essential amino acids found

in some dietary proteins cannot always be corrected by adding a single amino acid, the imbalance being the result of a deviation in several of the essential amino acids from an "ideal pattern" needed by the body. Multiple supplementation is generally required. This type of supplementation is at present best achieved by mixed diets where one food protein supplements another. The benefits to be derived from amino acid supplementation are uncertain until our knowledge of the consequences of the amino acid imbalance is more complete. The Food and Nutrition Board recognizes the potential value of proper supplementation with amino acids and the desirability of intensive study of this problem.

Education Projects for Retarded Children

Two cooperative research projects on the education of mentally retarded children were approved by the Office of Education, Department of Health, Education, and Welfare, in April 1957.

One of the projects, to be directed by Dr. Frances Mullen, assistant superintendent of schools of Chicago, will deal with the educational problems of mentally retarded children in special and regular classroom conditions. The Illinois State Department of Public Instruction and the city of Chicago will both participate.

The other project, with California participating, will be concerned with the effects of special training classes for severely retarded children. Dr. Leo Cain, dean of education services of San Francisco State College, will direct the project.

Sixty-six projects have been approved for cooperative educational research since September 1956. Thirty-nine of these concern education of the mentally retarded.

The Migrant and the Rest of Us

OTIS L. ANDERSON, M.D.

PUBLIC HEALTH workers, private physicians, and other local community residents are likely to have varied impressions of migrants depending on the angle from which they are viewed. The sanitarian sees the crowded housing of migrants with its lack of proper provision for sewage and garbage disposal and its water supply that may be polluted. The public health nurse who visits labor camps as part of her routine at the peak of the crop season sees cases of diarrhea, impetigo, malnutrition, and ear infections. The local physician and the hospital administrator see only people who come in an emergency when a serious accident or illness makes them seek medical care. Migrants may have few resources of their own for meeting an emergency. Nonresidence makes them ineligible for local welfare aid, and so some of their bills remain unpaid at the end of every crop season. The average person in a community is likely to view the migrant worker as a necessary part of the local economy, but potentially an economic burden if he stays beyond the season when he is needed. This same average person may fear the migrant as a potential disease carrier.

Only by putting all these views together can the migrant health problem be seen in its totality. For the Nation, the exact dimensions

of the problem are poorly defined. Twenty years ago a national health survey showed more frequent illness and longer-term disability among individuals and families on the move than among permanent residents. There is little evidence that the relative health status of the two groups has changed greatly in the last 20 years. Diarrheal disease continues to be common among migrant children. Outbreaks of typhoid and diphtheria continue to occur sporadically in migrant camps. All indications are that migrant children are probably less likely to be immunized against preventable diseases than resident children. Too often mothers fail to obtain prenatal care that will help to assure the health of both mother and child. Poor diets are common.

Number of People Involved

The national estimate of the number of migrants is approximately 1.25 million. Of these, nearly one-half million are foreign workers, chiefly from Mexico. These aliens are single men working under contract, with guarantees of work for stipulated periods of time. They are physically screened before they enter the country. Health insurance protection is given them under the terms of their contract. Housing for them must meet minimum requirements before they are assigned to an employer. When their contracts are fulfilled, the workers return to their own countries.

The tightening of our border patrol has nearly eliminated the wetbacks, illegal entrants, who formerly crossed the Mexican border in droves at harvest time.

The Migrant and the Rest of Us

OTIS L. ANDERSON, M.D.

PUBLIC HEALTH workers, private physicians, and other local community residents are likely to have varied impressions of migrants depending on the angle from which they are viewed. The sanitarian sees the crowded housing of migrants with its lack of proper provision for sewage and garbage disposal and its water supply that may be polluted. The public health nurse who visits labor camps as part of her routine at the peak of the crop season sees cases of diarrhea, impetigo, malnutrition, and ear infections. The local physician and the hospital administrator see only people who come in an emergency when a serious accident or illness makes them seek medical care. Migrants may have few resources of their own for meeting an emergency. Nonresidence makes them ineligible for local welfare aid, and so some of their bills remain unpaid at the end of every crop season. The average person in a community is likely to view the migrant worker as a necessary part of the local economy, but potentially an economic burden if he stays beyond the season when he is needed. This same average person may fear the migrant as a potential disease carrier.

Only by putting all these views together can the migrant health problem be seen in its totality. For the Nation, the exact dimensions

of the problem are poorly defined. Twenty years ago a national health survey showed more frequent illness and longer-term disability among individuals and families on the move than among permanent residents. There is little evidence that the relative health status of the two groups has changed greatly in the last 20 years. Diarrheal disease continues to be common among migrant children. Outbreaks of typhoid and diphtheria continue to occur sporadically in migrant camps. All indications are that migrant children are probably less likely to be immunized against preventable diseases than resident children. Too often mothers fail to obtain prenatal care that will help to assure the health of both mother and child. Poor diets are common.

Number of People Involved

The national estimate of the number of migrants is approximately 1.25 million. Of these, nearly one-half million are foreign workers, chiefly from Mexico. These aliens are single men working under contract, with guarantees of work for stipulated periods of time. They are physically screened before they enter the country. Health insurance protection is given them under the terms of their contract. Housing for them must meet minimum requirements before they are assigned to an employer. When their contracts are fulfilled, the workers return to their own countries.

The tightening of our border patrol has nearly eliminated the wetbacks, illegal entrants, who formerly crossed the Mexican border in droves at harvest time.

Dr. Anderson, Assistant Surgeon General of the Public Health Service, is chief of the Bureau of State Services. This paper is based on an address at the Friday morning session of the Twelfth National Conference on Rural Health in Louisville, Ky., March 8, 1957. The conference was sponsored by the Council on Rural Health of the American Medical Association.

Many workers are accompanied by family dependents.

The remaining three-fourths of a million in the agricultural migrant population are workers and their dependents who come chiefly from the southern border States. Texas is the largest single supply State and the greatest demand State. Unlike the foreign workers with contracts, these domestic agricultural workers, who are United States citizens, seldom work under contract. Few have health insurance protection, and standards for their housing are likely to be minimal.

While the domestic migrant works in sugar beets, cherries, potatoes, cotton, or beans, his pay may be relatively good. But periods of employment are balanced by periods of unemployment when the weather is bad, crops are poor, or work not available between crop seasons. Working time is also lost when workers are traveling from job to job. Most domestic migrant families lead a hand-to-mouth existence with an annual income of not more than \$2,000 even when several members of the family work. The average cash income of the male migratory farm worker, according to a

1954 national sample survey, was \$1,160. This includes income from both farm and nonfarm sources.

Economic Background

Seasonal work in agriculture requires a mobile labor force. As American agriculture has become bigger and more industrialized, machines have reduced the total number of man-hours of work required to produce the Nation's food and fiber. But some operations have not yet been mechanized nor for them does mechanization appear to be possible. Thus, for the greater part of a year, a relatively small labor force may be able to carry on the work of many crop areas. For a few short weeks or months, however, this labor force must be greatly expanded or the rest of the year's work will be lost. Some local workers can be recruited for short periods, but in many areas, the local labor supply must be supplemented by outside workers.

Available work changes with the seasons.

Family "housing" in a makeshift camp.

In the early spring the vegetable pickers are stooping over the fields in Florida, the Lower Rio Grande Valley, and southern Arizona and California picking the fresh carrots, beans, spinach, peas, celery, and lettuce that we serve on our dinner tables. These workers are chiefly southern Negroes, Puerto Ricans, Indians of the southwest, Spanish-Americans, including both domestic workers and Mexican nationals, and Anglo-Saxons from low-income farming areas in the south.

By the middle of the summer some of these same people are doing the same kind of work in New York State, Michigan, Montana, Colorado, Idaho, Washington, Oregon, and other northern States. At the end of the crop season, they will head south again in trucks, buses, and cars.

Impact on Local Health Resources

As stated earlier, the total number of domestic migrants is estimated at about three quarters of a million. A map of their movement,

however, makes it clear that this figure is not a true measure of the size of the problem (1). It has been said that the number might well be multiplied by the number of times people move. In each new location housing must be available. Local health workers must be ready to provide services if the health of both migrant and resident population is to be protected. Other community services must be stretched to accommodate the strangers.

The number of migrants of greatest importance in planning health services is not the national total, but the number in a particular locality at a particular time. All but two States have at least a few migrants for at least a short time. In many States, however, the area requiring farm workers from outside is exceedingly restricted. Of the total of 3,068 counties in the Nation, about 800 are estimated to have as many as 100 or more domestic migrant workers and family dependents at the peak of the season. Only about 75 counties have more than 3,000. Twenty-two of these counties, however, have more than 10,000 migrants at

A health center operated by a voluntary group in a labor camp.

the peak. The peak period may last for only a few weeks or for several months.

The impact of migrants on a county varies according to the size of the resident population and the availability of health resources. A county with 100,000 people may be fairly well equipped to care for the health needs of its permanent residents. Stretching these services to meet the needs of a few thousand temporary residents may require special planning but may not interrupt the usual routine very drastically. If, on the other hand, 10,000 or more migrants flock into an area whose resident population is no more than a few thousand, the health problems confronting local physicians and public health workers may be doubled overnight. Migrant work areas are predominantly rural, and many have a shortage of local health resources even for permanent residents.

Federal vs. Local Responsibility

The interstate aspects of the problem become clear from a look at the main routes migrants

travel. On the east coast, about 50,000 migrants start in the south in the spring and move back in the fall. From south Texas, at least 100,000 fan out to other parts of Texas and to the North Central, Mountain, and Pacific Coast States. Another 80,000 or 90,000 move within California and to adjacent States

Because of this interstate movement, some people have looked at migrant health as an interstate problem, one that might properly come under the jurisdiction of the Federal Government. On this basis, the Federal Government undertook the organization and financing of the agricultural workers' health associations during World War II. Local physicians and public health agencies worked through these associations with the Federal Government in providing services in major work areas along each of the main migrant routes. The major part of the financing came from the Federal Government. Federal funds were discontinued after 1947.

Today, pressures continue to be brought upon the Federal Government for financing

Well-maintained family units in a large labor camp.

migrant health care on the basis that the migrants are nonresidents and, therefore, not the responsibility of the State or local area where they work and live temporarily. On the other hand, some people are beginning to look upon migrants as part of the permanent population of an area even though they live there for only part of the year.

Local Efforts to Assume Responsibility

The view that migrant farm workers and their families are a permanent and essential part of the local economy is leading some localities to try to provide for them accordingly. Generally, these localities find that providing better housing, encouraging migrant children to go to school, and arranging for health services pay off in terms of greater assurance of dependable workers when they are needed and reduce chances of disease arising and spreading among both migrants and local residents.

Partnership between local medical societies and public health workers has been arranged in

Fort Lupton, Colo., Fresno County, Calif., and a few other areas. Local physicians and public health nurses have teamed up in staffing clinics held during workers' off-hours. These clinics provide services to prevent and control the spread of communicable disease. They also provide medical care for people who need it. They have been set up in places and at times convenient for the workers, many of whom do not have their own transportation and cannot well afford to lose time from work to bring their children in for immunization or to get treatment for sickness or injury.

Arrangements such as these are born of a need mutually recognized by local physicians, local public health workers, and other local residents. These workers, assisted by volunteers, have community support behind them. But even under the best circumstances many problems arise. With the best of planning, a newly opened clinic may attract only a handful of patients at first. Some of the first patients may be more curious than in need of care. Considerable patience is required. Public health

nurses may need to visit migrant families and encourage them to come to the clinic before there is any great demand for service. Once understanding and acceptance of the service have developed, however, the demand may well test the endurance of the staff.

One Clinic's Operation

A look might be taken into a clinic that has operated for about 5 years in a large labor camp in a building provided by the employer. On a typical day the clinic starts in the early evening. There are only a few patients at first, but more and more come until the small building is jammed. Some people have had to arrange with others for transportation. Many bring small children. There are 60 patients, but at least twice as many people are waiting.

A volunteer from a local women's organization takes down essential information at the reception desk. In a small room at one side, a public health nurse advises mothers on the care of their small children. In another room a physician from the local medical society, assisted by two public health nurses, is examining and treating a steady flow of patients. The local welfare agency pays each of the six physicians who serve on a rotating basis a set fee for each clinic session he conducts.

The cases seen include a child with a lacerated foot, a suspected case of tuberculosis referred to the county hospital for X-ray, a case of venereal disease, a sprained arm, several pregnant women, and two members of a family referred to the clinic because another family member has recently been hospitalized for typhoid fever.

A class in home nursing is conducted by a Red Cross volunteer in a small back room. Here, and in the waiting room, people seem to welcome the chance for sociability.

By agreement among the local medical society and other local agencies, the small fee that is supposed to be charged each patient is often waived. This is especially true when opportunity for work has been scarce in recent months and the families living in migrant camps have little or no money. Under such circumstances, local people believe that asking even a small fee will discourage people from

coming for needed care and defeat the purpose of the clinic.

Variation in Local Projects

The situation varies widely from place to place. Local needs differ and local resources for meeting these needs likewise differ. The migrant population group itself varies from one place to another, and these variations require different approaches if needs are to be served. Differences in language present an obvious problem when the Spanish-speaking migrant comes to a local physician or to a public health clinic in northern Michigan or Wisconsin. Differences in health beliefs and practices may be equally baffling to the physician or nurse who is trying to explain to a migrant mother how to care for her children.

Often there will be a need for supplementing local health resources when the migrant influx is at a peak. Some communities have found inactive local nurses who are willing to help in a migrant project. Physicians from nearby towns have participated in clinics set up in or near migrant camps. The Home Missions Division of the National Council of Churches, the Catholic Charities, women's organizations, and other groups have provided volunteer assistance in clinics, transportation and interpretation to migrants, and interpretation to communities at large of what a clinic was trying to do. Also they have financed services for individuals, and provided direct financial support for clinic operation. Employers and their associations may furnish a building for a clinic, assist in financing, or lend support in other ways. Farmers' wives and their organizations are still another source of interest, support, and active participation on a voluntary basis.

Role of Federal Agencies

Although local projects necessarily vary according to the local situation, they are likely to have certain needs in common. For example, a need that is repeatedly voiced by local physicians and public health workers is for some method of assuring continuity in the services provided as people move from place to place. Questions of how to finance health services

through voluntary health insurance and other means also frequently arise.

Other problems that confront most communities when they become interested in trying to meet migrants' health problems include adapting health services to population groups that differ markedly from the resident population in personal characteristics and in living and working conditions; developing community understanding of migrant problems; and encouraging community support in meeting them.

The major role of the Public Health Service is one of consultation and technical assistance to State and local groups in meeting these problems. Both the Public Health Service and the Children's Bureau have assisted in planning experiments with health records to be carried by migrant families. Although we do not feel that the experiments thus far have provided definitive answers to the problem of providing continuity of health services as migrants move, we have learned much that can be applied in a future study of this problem.

Another role, chiefly informational, has been passing on to new areas the ideas and plans that other communities have found successful. The Public Health Service has served from time to time as a catalyst to bring together individuals and groups concerned with specific health problems associated with the migration of agricultural workers and their families.

The philosophy in terms of the long-run interests of both the domestic migrant and the community, including the Nation as a community, is that migrants need to be viewed as an integral part of the general population. They form an essential part of our human resources. Their problems arise to a considerable extent from a mobility that is required by our agricultural economy in its present stage of development.

Special services may be required at times to meet emergency conditions. Generally, however, it seems desirable to meet the needs of migrants through the framework of existing community services for other citizens, with such modifications as may be necessary to meet the migrant's peculiar working and living conditions.

"The Rest of Us"

Certainly the whole Nation profits by migrant labor. Much of the food that reaches our family tables is harvested and processed by migrant workers. The communities where migrants work and live temporarily profit most of all. Sometimes local people say, "We have no responsibility for migrants. They don't pay taxes." Some of these same people might find it difficult to pay their own taxes if migrants failed to appear at the critical times in crop production and harvesting.

All of us have a responsibility for understanding the important contribution the agricultural migrant makes to our economy. We have a further responsibility for helping him and members of his family share in community services on a continuing basis, including health services. The Public Health Service is sincerely interested in helping to identify the health problems both of the person who is on the move and of the communities to which he returns for a short time each year and to plan for meeting these problems.

use of general hospitals

Factors in Outpatient Visits

MAURICE E. ODOROFF, M.A.

LESLIE MORGAN ABBE, B.S.

AS PART of a study of the use of general hospitals, the level of use of outpatient facilities in relation to various personal, geographic, and economic factors has been investigated. Data were obtained through interviews of about 27,000 households, including about 90,000 persons of all ages, drawn from the civilian, noninstitutional population of every State in the United States. Selected highlights of the findings on outpatient visits are reported here as advance information.

In the course of each interview, the respondent was asked whether anyone in the household had received care in any hospital without staying overnight, "for example, in a hospital clinic, emergency room, outpatient department, etc." For each person identified as having received outpatient care, the name and location of hospitals visited and the number of visits made for outpatient care during the previous 12 months were recorded. Personal characteristics of each member of the household and the income level of each household were also

learned. In tabulating results, particular attention was given to determining the place of care with respect to the type of place of residence (metropolitan, urban, or rural) of the patient.

The survey findings are limited by the exclusion of institutional populations, the absence of data on hospital use by persons who died, emigrated, or entered the armed services before the survey date, and the normal variability of sampling. In addition, note should be made of the possibility of errors in response with respect to the data on outpatient visits. The frequency of outpatient visits may not be remembered as completely as the frequency and extent of inpatient care. Earlier experience in health surveys indicates a considerable loss of recall when the period of time elapsed between the occurrence and the reporting is extensive, unless the event was important in itself to the person interviewed or was associated with significant points in time or other distinguishing factors (1, 2). In this survey differentials in use are more important than definitive levels of use. Accordingly, while under-reporting may affect the general level of use, it is considered of minor consequence.

Two basic measures have been selected to

Mr. Odoroff is chief, and Mr. Abbe is assistant chief, Program Evaluation and Reports Branch, Division of Hospital and Medical Facilities, Public Health Service.

This paper is the second interim report setting forth provisional findings of a national household survey of the use of general hospitals. The first, published in the May 1957 issue of *Public Health Reports* (pp. 397-403), briefly described the survey procedure and presented findings on demographic and ecologic factors in the use of inpatient facilities. Analysis and interpretation of the data will be included in a summary monograph when the study is completed.

The survey is considered a first step in defining more precisely appropriate standards of need for general hospitals in the light of changing medical practice and changing patterns of care. It is expected to point the way to more intensive studies of the real need for physical facilities for adequate care of a known and described population. The survey was conducted for the Division of Hospital and Medical Facilities of the Public Health Service in September 1956 by the Bureau of the Census in connection with its monthly current population survey.

describe the level of outpatient visits in varying circumstances. These are the number of outpatients receiving care annually per 1,000 population and the number of outpatient visits annually per 1,000 population. The volume of outpatient care reflected by these measures is set forth in comparison with three types of factors. One group of factors, relating to personal characteristics, may be considered demographic factors. Another group relates to the nature of the geographic and social setting of the place of residence and the place of care. In this study, these are called ecologic factors. A third factor is family or individual income.

Demographic Factors

Sex and race have very little effect on the number of outpatients cared for, but they do affect greatly the number of outpatient visits (table 1).

Outpatient visits of white persons number 151 annually per 1,000 population, while visits of nonwhite persons amount to 238 per 1,000 population. For the nonwhite population,

similar contrasts appear between men and women; nonwhite males report 188 visits, while nonwhite females report 285 visits. In the white population, only small differentials appear between visits of men and women.

Age affects the number of outpatients only slightly, except that a higher rate is found for children, but total outpatient visits rise substantially with age (table 2).

For children under 14 years of age, the number of outpatients, 58 per 1,000 population, is well above that of other age groups and the average (47) for all ages.

The number of outpatient visits is highest for the age groups above 45 years. The maximum is 251 visits for the age group 55-64 years, as compared with 161 visits for all ages and 98 visits for adolescents and young adults (ages 14-24 years).

Table 1. Outpatient care in general hospitals, by sex and race

| Sex and race | Annual number of outpatients per 1,000 population | Annual outpatient visits per 1,000 population |

| Other nonworkers..... | 48 | 249 |

¹ Includes forestry and fisheries.

veterans, among all males 14 years old and over.

Employment status and industry are accompanied by substantial differences both in the number of outpatients and in total outpatient visits (table 4).

For all persons 14 years of age and over, the number of outpatients cared for annually is 42 per 1,000 population. Within the labor force the number ranges from 32 for those employed in agriculture to 66 for wage and salary workers in mining (including forestry and fisheries). A similar high rate of 67 patients per 1,000 population is reported for persons unable to work because of a long-term illness or disability.

Total outpatient visits vary even more widely. The average rate for all persons employed is 123 visits annually per 1,000 population. Persons in agriculture report only 83 visits per 1,000 population, with a maximum among employed persons of 173 visits for wage and salary workers in mining. Unemployed workers and persons keeping house report a rate of visits of 222 and 231 per 1,000

² Less than 0.5.

population. Persons unable to work report an annual rate of 822 outpatient visits, an average of slightly more than 1 visit per month per person in this group receiving care.

Ecologic Factors

Geographic region and type of residence have a limited effect on the number of outpatients but a very substantial effect on the number of outpatient visits (table 5).

The number of outpatients among persons who live in rural areas is low in the Northeast and North Central regions of the country (38 and 36 annually per 1,000 population), but is well above national averages in the South and West (49 and 58 annually per 1,000 population).

These differentials apply also to total outpatient visits of rural people. On the other hand, urban residents in the Northeast and West have a comparatively high number of outpatient visits annually (234 and 200 per

1,000 population). Rates are well below the national average for urban persons in the North Central region and in the South (147 and 137 visits annually per 1,000 population).

Type of residence and place of care, as they reflect accessibility, materially affect the level of outpatient visits (table 6).

The annual rate of outpatient visits from all types of residence in all places of care is 161 per 1,000 population.

Persons living in the central city of metropolitan areas report a rate of 232 visits. Outpatient visits drop to 143 for urban fringe residents and reach a low of 69 for persons from farms in the outer limits of metropolitan areas.

Outpatient visits by persons living in cities of 10,000-50,000 population not in metropolitan areas are reported at 133, while visits by persons living in nonmetropolitan rural areas are reported at 145 per 1,000 population.

Residents of the urban fringe of metropolitan areas make about three-fifths of their

total outpatient visits within the central city of the metropolitan area in which they live. Urban and rural residents of nonmetropolitan areas obtain the major portion of their outpatient care in their home communities, although from 10 to 20 percent of such care is obtained in metropolitan areas.

Economic Factor

Income and family status have a substantial relation to the level of outpatient care received, at least with respect to the number of visits (table 7).

Among members of primary families, that

is, persons related by blood, marriage, or adoption to the head of the household in which they live (3), the maximum number of outpatient visits is made by persons in the lowest income groups. The rate for all members of primary families decreases from 199 visits per 1,000 population for income groups under \$1,000 to 106 visits for the income range \$5,000-\$10,000. Families with incomes over \$10,000 are reported at an increased rate of 144 visits.

Children under 14 years of age in the lowest income group (under \$1,000) have a very low rate of visits (59 per 1,000 population), although adults in families in this income group

Table 7. Outpatient care in general hospitals, by income, family status, and age

| Income ¹ | Family status ² and age | | | |
|---|------------------------------------|---------------------------|------------------------|---------------------|
| | Members of primary families | | | Primary individuals |
| | All members | Members 14 years and over | Members under 14 years | |
| Annual number of outpatients per 1,000 population | | | | |
| All incomes..... | 46 | 42 | 57 | 60 |
| Under \$1,000..... | 41 | 46 | 27 | 81 |
| \$1,000-\$1,999..... | 49 | 47 | 53 | 65 |
| \$2,000-\$2,999..... | 50 | 47 | 56 | 45 |
| \$3,000-\$3,999..... | 49 | 43 | 62 | 42 |
| \$4,000-\$4,999..... | 48 | 42 | 60 | 35 |
| \$5,000-\$7,499..... | 45 | 37 | 61 | 51 |
| \$7,500-\$9,999..... | 46 | 41 | 61 | |
| \$10,000 and over..... | 44 | 43 | 48 | |
| Income not reported..... | 34 | 29 | 52 | 26 |
| Annual outpatient visits per 1,000 population | | | | |
| All incomes..... | 151 | 160 | 128 | 328 |
| Under \$1,000..... | 199 | 256 | 59 | 545 |
| \$1,000-\$1,999..... | 197 | 202 | 185 | 395 |
| \$2,000-\$2,999..... | 194 | 211 | 156 | 183 |
| \$3,000-\$3,999..... | 146 | 139 | 159 | 152 |
| \$4,000-\$4,999..... | 177 | 200 | 133 | 144 |
| \$5,000-\$7,499..... | 106 | 102 | 114 | 89 |
| \$7,500-\$9,999..... | 105 | 110 | 90 | |
| \$10,000 and over..... | 144 | 167 | 68 | |
| Income not reported..... | 119 | 126 | 97 | 47 |

¹ For members of primary families, "income" includes money income of all members of the family; for primary individuals, it includes personal income only.

² Primary family members include persons related by blood, marriage, or adoption (one of these persons being the head of the household). Primary individuals are heads of households not living with relatives (see reference 3).

report a level more than 4 times as great. Except for this lowest income group, the data reported for primary families show rather close parallels for annual outpatient visits by children and adults.

Primary individuals, that is, heads of households not living with relatives (9), with incomes under \$2,000 report a rate of outpatient visits greatly in excess of the outpatient visits made by adults in primary families with similar incomes. The rate reported among primary individuals in the income group under \$1,000 is 545 visits per 1,000 population; among those in the group \$1,000-\$1,999, it is 395 visits per 1,000 population.

Summary

This is the second interim report on a national household survey of the use of general hospitals by a known population. Data have been compiled from a sample comprised of about 27,000 families, including about 90,000 persons of all ages. This report records provisional findings on factors related to the level of outpatient visits to general hospitals. These factors include demographic, ecologic, and economic aspects.

The most significant contrasts in level of outpatient use appear for variations in income levels. Families with incomes below \$2,000 are reported as making about 200 outpatient

visits annually per 1,000 population, while those with incomes between \$5,000 and \$10,000 report about one-half of this rate. Primary individuals (household heads not living with relatives) in the income groups below \$2,000 report outpatient visits at a level double that of adults in primary families with the same income.

Substantial differences in the rate of outpatient visits accompany variations in race, sex, age, and employment status. Place of residence appears also to have a considerable effect on the rate of outpatient visits. The rate is highest for residents of the central city in metropolitan areas and lowest for the rural farm population in metropolitan areas. The rate of outpatient visits for the farm population outside metropolitan areas is only slightly below the national average for all persons.

New Site for National Library of Medicine

The proposed new building for the National Library of Medicine will be constructed on the grounds of the Public Health Service's National Institutes of Health in Bethesda, Md. Selection of a site for the library was made by the board of regents of the library at its second meeting on April 29, 1957.

Factors leading to the choice of the specific site were its proximity to two large medical centers, the availability of sufficient land, a good network of transportation, and established supporting services and facilities.

Climate and Fluid Intake

DONALD J. GALAGAN, D.D.S., M.P.H., JACK R. VERMILLION, M.P.H.,
GEORGE A. NEVITT, D.D.S., M.P.H., ZACHARY M. STADT, D.M.D., M.P.H., and RUTH E. DART, M.P.H.

NUMEROUS investigators have studied the physiological reaction of adults to specific temperature, humidity, and other variable climatic conditions (1, 2). These studies, initiated primarily by the U. S. Armed Forces, have been concerned largely with man's comfort, efficiency, or survival in the desert, arctic, or other places with severe climatic conditions. There have been a few investigations of the physiological response of children to heat stress under laboratory (3) and normal living conditions (4, 5), but data are too limited to describe adequately the influence of climatic factors on the amount and kind of fluid consumed by this group.

Interest in the physiological response of children to climate increased markedly with the advent of community water fluoridation. Epidemiological studies in natural fluoride areas have shown that 1 p.p.m. fluoride represents the optimum level for dental caries con-

trol in most of the United States (6). However, it has been suggested that in the practical application of the findings less than 1 p.p.m. may be sufficient to give optimum protection in very warm areas because of increased water consumption (7).

Galagan and Lamson (8) using two biological indexes (fluorosis and dental caries) found that Arizona children, living in a climate where the mean annual temperature is approximately 70° F., had a higher fluorosis index and a lower caries rate than children who used water with the same fluoride concentration but who lived in the midwest where the mean annual temperature is 50° F. They concluded that the Arizona residents drink more water than children living in the more temperate climate.

Since this finding and an earlier pilot study (5) indicated that climatic factors do influence water consumption in children, it was decided to investigate the relationship between climate and fluid intake more extensively by measuring, under normal living conditions, the actual amounts of fluid consumed by a large number of children exposed to varying climatic conditions. The study was undertaken jointly by the Public Health Service and the Contra Costa County (Calif.) Health Department, with active support from superintendents, principals, teachers, and nurses of local schools and members and officers of local parent-teacher associations.

The Field Study

Antioch and Brentwood in Contra Costa County, Calif., were selected as study sites. Both communities experience temperatures

Dr. Galagan is assistant chief, and Mr. Vermillion is public health adviser, Division of Dental Public Health, Public Health Service. Dr. Nevitt is regional dental consultant for the Public Health Service in Region 9, San Francisco, Calif. Dr. Stadt is assistant health officer, Contra Costa County Health Department, Martinez, Calif. Miss Dart, now with the San Joaquin County Health Department, Stockton, Calif., was formerly a public health research analyst with the Public Health Service in Region 9.

Dr. Henrik L. Blum, health officer of Contra Costa County, assisted in carrying out the study reported in this paper. Dewey DiMartini, Mrs. Elsie M. Green, and Mrs. Evelyn G. Ackerman served as volunteer weather observers in Brentwood, and Edward C. Jennings, in Antioch.

above 90° F. each summer, and both have mild winters, but there is enough difference between the winter and summer months to permit evaluation of seasonal change.

In a series of thirty-nine 5-day study periods during approximately 1 year, records of fluid intake were obtained for 316 Antioch and 139 Brentwood children. In Antioch, there were 27 periods, Monday through Friday, every other week, from November 30, 1953, through December 3, 1954. In Brentwood, data were obtained for one 5-day week each month from January 25, 1954, through December 10, 1954.

The participating children were divided into study groups of 12, a boy and girl in each of 6 age groups ranging from infancy through 10 years. The fluid consumed by each child was recorded for a 5-day period. No child participated for more than one period. With a few exceptions, the participants were distributed equally by sex throughout all six age groups in each study period. In a few instances records were maintained for a given child for fewer than 5 days, and occasionally fewer than 12 children participated in a group. All calculations take these irregularities into account. The age and sex distribution of participants is shown in table 1.

Table 1. Number of participants, by age and sex, Antioch and Brentwood, Calif.

| Age in years | Antioch | | | Brentwood | | |
|--------------|---------|------|-------|-----------|------|-------|
| | Total | Boys | Girls | Total | Boys | Girls |
| All ages | 316 | 156 | 160 | 139 | 68 | 71 |
| Under 1 | 54 | 27 | 27 | 19 | 8 | 11 |
| 1-2 | 52 | 25 | 27 | 24 | 12 | 12 |
| 3-4 | 54 | 27 | 27 | 24 | 12 | 12 |
| 5-6 | 54 | 27 | 27 | 24 | 12 | 12 |
| 7-8 | 51 | 26 | 25 | 24 | 12 | 12 |
| 9-10 | 51 | 24 | 27 | 24 | 12 | 12 |

The children studied were selected from a roster of potential participants for each town. The rosters were divided into sections according to sex and age groups, and the names of the children in each section were arranged alphabetically. In accordance with a prescribed sampling procedure, the names of possible participants were drawn from the roster. If the

parents of a selected child did not agree to participate during the full 5-day period, an alternate child was chosen. Children who were known to be ill were excluded, especially if they had fever. Since participation in the study was voluntary, the children included do not necessarily comprise a sample representative of all children in the two communities.

Each participant was visited at home at least three times. The first visit was made to obtain a firm commitment from the parents that their child would participate and to instruct the parents and the child how to measure and record fluid intake. A plastic cup, calibrated in fluid ounces, and a record book were given to the parents. For each school child, a collapsible cup, also calibrated in fluid ounces, and an additional booklet were issued to the child's teacher, who was given the same instructions as the parents. Teachers of kindergarten and first-grade children maintained the records during school hours, but children in the second grade and above usually maintained their own fluid consumption records, with some teacher supervision.

The second visit took place at the midpoint of the recording period. The child was weighed, any problems in maintaining the fluid-consumption record were discussed, and the record was checked for obvious errors or omissions. The third visit was made at the end of the recording period. The fluid-consumption records were collected from the homes and the schools and were given a final review at this time.

The amount of fluid consumed was recorded in eight categories. The first five categories included either water in its natural form or substances to which water is added in the home: drinking water, formula preparations for babies or reconstituted milk made with water, juices diluted with water, soups diluted with water, and other water-based beverages such as tea or coffee. The other three categories included beverages which do not have water added in the home: carbonated beverages, juices not diluted with water, and other beverages such as whole milk. Water used in cooking, such as that added to vegetables, was not recorded.

The United States Weather Bureau installed

and maintained the equipment needed for recording climatologic observations in each community. The equipment consisted of maximum and minimum thermometers, wet and dry bulb thermometers, a fan, and a hygrothermograph for recording temperature and humidity continually during a 24-hour period. Since the Weather Bureau staffs its weather stations with volunteers, volunteers were recruited in each community to serve as weather observers. They read the wet and dry bulb thermometers and recorded the dew point three times each day, 9 a. m., noon, and 5 p. m. They read the maximum and minimum thermometers once each day and recorded rainfall whenever it occurred. The data from the hygrothermograph were checked against the manual observations, and any necessary changes were made in the data according to procedures outlined by the Weather Bureau climatologist.

Climatologic Findings

Two of the most common expressions of climate are temperature and humidity. However, no one of the many measures of temperature or

humidity is recognized as the best measure of these factors. Among the possible ways temperature or humidity can be expressed are the 24-hour mean, the 7 a. m. to 6 p. m. mean, the daily maximum, the mean of the maximum and the readings on the hours preceding and following the hour in which the maximum occurs, the 3 p. m. reading, and the daily mean calculated by averaging the maximum and minimum.

From a practical standpoint, all six measures could not be used in the analysis. To identify the ones that reflect most accurately the climatic conditions to which the children in the study were exposed, rank order correlations of these measures were done.

For temperature, an average of each of the aforementioned expressions was calculated for each observation period during which fluid-intake records were maintained, and each of the measures was then ranked according to the period in which the particular expression ranked highest, next highest, and so on. Coefficients of concordance were 0.986 for Antioch and 0.975 for Brentwood. Since the correlation between the rankings of the various temperature expressions is so high, it may be concluded

that any one of the measures is as good as any other to describe the temperature factor in this climatic environment. The daily maximum temperature is used here since it reflects the extremes of heat to which an individual is exposed and since it is a measure generally available wherever weather observations are recorded.

For the rank order correlation of humidity expressions, minimum humidity was used instead of maximum humidity since the latter approached 100 percent at some time nearly every day, particularly in the early morning hours. The result of the correlation is similar to that for temperature, and it is concluded that any one of these measures of humidity adequately describes the humidity factor in this climatic environment.

It has been assumed by many investigators that humidity has an important effect on fluid intake, although the extensive observations re-

and maintained the equipment needed for recording climatologic observations in each community. The equipment consisted of maximum and minimum thermometers, wet and dry bulb thermometers, a fan, and a hygrothermograph for recording temperature and humidity continually during a 24-hour period. Since the Weather Bureau staffs its weather stations with volunteers, volunteers were recruited in each community to serve as weather observers. They read the wet and dry bulb thermometers and recorded the dew point three times each day, 9 a. m., noon, and 5 p. m. They read the maximum and minimum thermometers once each day and recorded rainfall whenever it occurred. The data from the hygrothermograph were checked against the manual observations, and any necessary changes were made in the data according to procedures outlined by the Weather Bureau climatologist.

Climatologic Findings

Two of the most common expressions of climate are temperature and humidity. However, no one of the many measures of temperature or

humidity is recognized as the best measure of these factors. Among the possible ways temperature or humidity can be expressed are the 24-hour mean, the 7 a. m. to 6 p. m. mean, the daily maximum, the mean of the maximum and the readings on the hours preceding and following the hour in which the maximum occurs, the 3 p. m. reading, and the daily mean calculated by averaging the maximum and minimum.

From a practical standpoint, all six measures could not be used in the analysis. To identify the ones that reflect most accurately the climatic conditions to which the children in the study were exposed, rank order correlations of these measures were done.

For temperature, an average of each of the aforementioned expressions was calculated for each observation period during which fluid-intake records were maintained, and each of the measures was then ranked according to the period in which the particular expression ranked highest, next highest, and so on. Coefficients of concordance were 0.986 for Antioch and 0.975 for Brentwood. Since the correlation between the rankings of the various temperature expressions is so high, it may be concluded

Relationship between daily maximum temperature and water intake among children, Antioch and Brentwood, Calif.

negative relationship, significant at the 5 percent level, was demonstrated between other fluids (milk and all other fluids which do not contain water added in the home except carbonated beverages) and temperature, both with and without body weight equated.

The only major differences found for Brentwood were these: Temperature did not correlate significantly with carbonated beverages or with other fluids (as defined in the preceding paragraph); correlations of temperature with total fluid and with drinking water were significant at the 5 percent level without body weight equated and at the 1 percent level with body weight equated.

The significant negative correlation demonstrated in Antioch between temperature and intake of fluids other than water, water-based beverages, and carbonated beverages may result from a decrease in intake of milk as tempera-

ture increases and water and cooling drinks are substituted for milk. This pattern of behavior has been observed previously in infants (3).

Of primary interest are the water consumption data in table 4 for two periods, November through March, when the temperature averaged 60° F., and April through October, when the temperature averaged 82° F. A decided shift to greater water intake during the higher temperature period is reflected in these data. However, under conditions of both high and low temperature, more than 90 percent of the children drank less than 1 ounce of water per day per pound of body weight. No such shift was discernible in the consumption of fluids other than water.

The relationship between temperature and water consumption is shown more precisely in table 5 and in the chart. The plotted points on this chart represent the mean amounts of water

possible additional effect of humidity on fluid intake, did not occur in the study communities. For example, in Antioch there were 66 hourly observations of temperatures of 90° F. or higher during the recording periods. For the same hours, humidity did not exceed 39 percent and often went below 20 percent. Analysis of the relationship between humidity and fluid intake will not be presented since a correlation between the mean maximum temperature and the mean minimum humidity in each community demonstrated an inverse relationship approaching unity. This inverse relationship between temperature and humidity is not limited to the western United States; in fact, it appears to be a common phenomenon (9, 10).

Studies of man in the tropics indicate that relative humidity up to 80 percent does not add to thermal stress (1). It is unlikely, therefore, that humidity has an important influence on fluid intake among children. However, further study of the possible independent effect of humidity on fluid intake in areas where high temperature and high humidity occur simultaneously may be indicated. One such area is adjacent to the Gulf of Mexico.

Temperature and Fluid Intake

In this report the term "temperature" refers to mean maximum temperature for the periods that data on fluid intake were recorded. The term "fluid" refers to all fluids consumed. Other types of fluids are mentioned specifically by name when comments refer to them. Data for both Antioch and Brentwood are presented in each table, but unless otherwise specified only the Antioch data are discussed. Since fewer than half as many observations were made in Brentwood as in Antioch, the Brentwood data do not have the same degree of reliability as those for Antioch. Generally speaking, the findings for Antioch hold true for Brentwood.

Both total fluid intake and water intake per pound of body weight decreased with increase in age, as shown in table 2. This decrease resulted mainly from the increase in body weight with age, not from an actual decrease in the total amount of fluid consumed. Correlations of both total fluid intake and water intake with

body weight are significant at the 1 percent level, although the correlations are not unity. Thus, a 10-year-old child drinks more fluid than an infant, but not in direct proportion to the weight difference between the two individuals. No important differences between boys and girls in the amount of fluid consumed are apparent.

Water accounted for about 43 percent of the total fluid consumed (table 3). Slightly less than one-half of the fluid consumed was milk. This amount represents fluid milk and does not include formula preparation made with a water base or with powdered milk reconstituted with water. Carbonated beverages and other fluids combined made up less than 9 percent of the fluid intake of the children.

Table 5. Mean maximum temperature and water intake for each recording period, Antioch and Brentwood, Calif.

| Mean maximum temperature for recording period | Ounces of water consumed per child per day per pound of body weight | Mean maximum temperature for recording period | Ounces of water consumed per child per day per pound of body weight |
|---|---|---|---|

| 78.2----- | .44 | 80.8----- | .56 |
| 80.6----- | .34 | 82.6----- | .49 |
| 80.8----- | .38 | 84.0----- | .58 |
| 81.0----- | .40 | 85.6----- | .57 |
| 81.8----- | .33 | 89.2----- | .45 |
| | | 97.6----- | .55 |

Correlations of temperature with total fluid, with drinking water, with water-based beverages (as defined), with total water, and with carbonated beverages were significant at the 1 percent level. Correlations were equally significant when body weight was equated to account for the possible effect that weight differences might have on fluid consumption. A

Determining Optimum Fluoride Concentrations

DONALD J. GALAGAN, D.D.S., M.P.H., and JACK R. VERMILLION, M.P.H.

On the basis of the fluid intake study in Antioch and Brentwood, Calif., reported on pp. 484-490, Dr. Galagan and Mr. Vermillion, of the Public Health Service, have developed the method described here for determining optimum fluoride concentrations in water supplies. This method takes into account the effect of environmental temperature on water consumption among children.

THE FLUID intake study among children in Antioch and Brentwood, Calif., in 1953-54 provides a basis for determining the optimum fluoride concentration in water supplies in relation to environmental temperature. This study showed that for every degree increase in maximum daily temperature between 50° and 100° F. water intake increased, on the average, by 0.062 ounces per pound of body weight. For example, the average daily water consumption per pound of body weight was 0.272 ounces when the maximum daily temperature was 50° F. and 0.334 ounces when the maximum daily temperature was 60° F.

The relationship between maximum temperature and water intake for the California children was described by the estimation equation "ounces of water per pound of body weight = $-0.038 + 0.0062 \text{ temperature}$." The validity of this equation should perhaps be checked by studies in other areas of the country, but in the meantime it can be used to illustrate the calculation of optimum fluoride concentrations. As will be pointed out later in the paper, results obtained with the equation in the Chicago area, where optimum fluoride concentration is known from epidemiological studies, indicate that it is reasonably reliable.

The basic structure of the formula developed for estimating optimum fluoride concentrations is: parts per million of fluoride = opt-

imum water consumption ÷ estimated water consumption. Thus, the optimum fluoride concentration for a given community is equal to a constant (the average amount of water containing 1 p.p.m. fluoride that affords optimum protection against dental caries) divided by the estimated water consumption of children in a given community. Both measures are in ounces of water consumed daily per pound of body weight.

If daily maximum temperature data for the Chicago area are applied to the water estimation equation, it is possible to calculate a denominator value for the formula, that is, the average amount of water that would be consumed daily per pound of body weight by children in the Chicago area aged 10 years or less. The number derived, although it has no particular meaning in itself, may also serve as the constant for the formula, since it is known from epidemiological data that the optimum fluoride concentration for the Chicago area is 1 p.p.m. The constant, or numerator, in the formula must equal the estimated water consumption, or denominator, for the optimum fluoride concentration to be 1 p.p.m.

The estimated water consumption for the Chicago area children is based on weather data for two towns, Maywood and Joliet. Since both of these towns were included in the early studies of Dean (1), the fluoride concentration

consumed per child per day per pound of body weight for each recording period in each community. The line is derived from the estimation equation "ounces of water per pound of body weight = $-0.038 + 0.0062$ temperature," based on the data in table 5.

The findings for the two communities so closely approximate each other that data for both Antioch and Brentwood were used as the basis for deriving the equation that describes the relationship between temperature and water consumption. A straight line was calculated but the line should not be extended beyond the maximum temperature range of 50° to 100° F.

The line representing water consumption rises as temperature increases. This relationship has been described earlier by the positive correlation between water consumption and temperature. It may be concluded from these observations that the direct method of measuring water intake in children exposed to varying temperatures, under normal living conditions, confirms earlier observations obtained by using indirect biological measurements that the amount of water consumed by children increases with increases in temperature.

Summary

1. Records of fluid intake for 455 Antioch and Brentwood, Calif., children from infancy through 10 years of age were obtained during thirty-nine 5-day observation periods in a period of 1 year. Detailed temperature and humidity data also were obtained throughout the year.

2. Rank order correlations showed that any one of several expressions could be used to describe the climatic variables, temperature and humidity. Maximum temperature and minimum humidity were selected as the expressions of choice.

3. Humidity was associated negatively with temperature to such a high degree that it was

not possible to determine whether humidity might have some additional effect on fluid consumption in areas where high temperature and high humidity occur simultaneously.

4. Fluid intake per pound of body weight was highest among infants and decreased with age.

5. There were no substantial differences between boys and girls in the amount of fluid consumed per pound of body weight.

6. Under normal living conditions, water intake increased directly with increases in temperature.

mum fluoride levels for ranges of mean maximum temperatures from 50° through 90.5° F. are presented in table 2. The optimum fluoride concentration for a community may be determined simply by obtaining the mean maximum temperature for a 5-year or longer period from appropriate publications of the United States Weather Bureau and then referring to this table.

Two points must be stressed in the application of this method. First, the temperature figure should be at least a 5-year average for the figure to be truly representative. Second, the mean maximum temperature in degrees Fahrenheit is the only measure that can be used since the method is based on an equation for estimating water consumption in which this measure is used.

Summary

The following formula, which takes into account variations in environmental temperature, is suggested for determining optimum fluoride concentrations for community water supplies:

$$\text{parts per million of fluoride} = \frac{0.34}{E}$$

The figure 0.34 (optimum water consumption) was calculated from data for an area where the optimum fluoride concentration is known. E is the estimated average daily water intake for children through 10 years of age in ounces per pound of body weight. It may be calculated from the estimation equation $E = -0.038 + 0.0062$ temperature, where temperature is the mean maximum temperature in degrees Fahrenheit.

A table showing suggested optimum fluoride concentrations for communities with 5-year mean maximum temperatures of 50° through 90.5° F. is presented.

Training in Care of Prematures

The institutes for physicians and nurses in the care of premature infants at the New York Hospital-Cornell Medical Center will begin their ninth year in the fall of 1957. The institutes are sponsored by the New York State Department of Health and the Children's Bureau.

The training is designed for physicians and nurses in charge of hospital premature nurseries and premature centers, and medical and nursing directors and consultants in State and local premature programs.

Attendance at each institute is limited to six physician-nurse teams. The program for physicians lasts 2 weeks and that for nurses, 4 weeks. Participants pay no tuition fee, and stipends are provided to help cover expenses during attendance. Institutes are scheduled to start on September 30, 1957, November 18, 1957, and January 6, 1958. If the number of applicants is sufficient, fourth and fifth institutes will be scheduled, beginning March 3, 1958, and late in April or May 1958.

For additional information write to Box 143, Institute in the Care of Premature Infants, New York Hospital, 525 East 68th Street, New York 21, N. Y.

¹ Based on temperature data for the 5-year period 1951-55 from U. S. Weather Bureau publications entitled "Climatological Data."

and the fluorosis index are known. Although both communities have more than 1 p.p.m. of fluoride in their water supplies, 1 p.p.m. is considered the optimum concentration.

The estimated average water consumption, the denominator of the formula, which is hereafter called *E*, is calculated by obtaining the mean maximum temperature for at least a 5-year period for the community in question and substituting this figure in the estimation equation $E = -0.038 + 0.0062 \text{ temperature}$. The resulting value represents the average number of ounces of water per pound of body weight that children through 10 years of age would be expected to drink daily under the temperature conditions of the community. The *E* value for both Maywood and Joliet is 0.34, and, as explained previously, this number may serve as the constant for the formula.

The value 0.34 for the constant is reasonable from the standpoint of optimum fluoride ingestion through water. For example, again in terms of average phenomena, 0.34 ounces of water fluoridated at 1 p.p.m. contains approximately 0.011 mg. of fluoride. In the fluid intake study in California, the average body

weight of children studied was about 46.5 pounds. At this weight, the children ingest about 0.5 mg. of fluoride daily through their drinking water. This amount is similar to other estimates of the amount of fluoride that should be ingested through water for optimum dental health (2). This fact tends to strengthen confidence in both the constant and the water estimation equation from which it was derived.

With the formula "parts per million of fluoride = $0.34 \div E$," optimum fluoride concentrations have been calculated for selected communities representing various geographic areas throughout the United States. The results are shown in table 1. For the cities listed, the lowest concentration, 0.7, is suggested for the Arizona communities; the highest, 1.2, for Butte, Mont.

To obtain a fluoride concentration lower than 0.7 p.p.m. with this formula, the mean maximum temperature would have to average at least 90.6° F. To obtain one greater than 1.2 p.p.m., the mean maximum temperature would have to be lower than 50° F. The possibility of the occurrence of either of these extremes in the United States seems remote. Consequently, it is not expected that the optimum concentration for any community would be outside the range 0.7-1.2 p.p.m. generally recommended for fluoridation.

In the practical application of the method described here for determining optimum fluoride concentrations, it is not necessary to make calculations for each community. Opti-

Table 2. Mean maximum temperatures and corresponding recommended optimum fluoride concentrations

| Mean maximum temperature (degrees Fahrenheit) | Recommended optimum fluoride concentration (parts per million) |
|---|--|
| 50.0-53.7 | 1.2 |

| 58.4-63.8 | 1.0 |
| 63.9-70.6 | .9 |
| 70.7-79.2 | .8 |
| 79.3-90.5 | .7 |

Service Statistics Series

A series of documents on the collection, analysis, and interpretation of service statistics for various health department programs is being developed by the Working Group on Service Programs, Public Health Conference on Records and Statistics.

An introduction to the series and the basic principles governing service statistics in public health appeared in June 1956, Public Health Reports, page 519. These were followed in the July issue, page 705, by a statement on service statistics for the health supervision of infants and preschool children. Statistics on health services for children of school age was the subject of the third report, published in September 1956, page 917.

In developing this fourth report, which is a guide to statistical services in the planning, administration,

and evaluation of public health services in home accident prevention, the working group had the assistance of several consultants with especial experience in programs for the prevention of home accidents.

This report was approved by the conference membership in the autumn of 1956. It was reproduced in mimeographed form as attachment A to document 370 by the National Office of Vital Statistics, Public Health Service, Department of Health, Education, and Welfare, Washington, D. C. It has the endorsement of the Statistics Section and the Committee on Administrative Practice of the American Public Health Association, the National Safety Council, and the Council of State Directors of Public Health Nursing.

In addition to assessing the extent and severity of the problem, there is need for taking stock of present activities in the field. The Proceedings of the First and Second Michigan Conferences on Home Accident Prevention (2) discuss facts, figures, and findings. The individuals, families, or groups served by public health and allied workers should also be studied. Analysis of the causes of accidental injuries and deaths is a means of identifying and substantiating specific problem areas (3-6).

The following items are suggested guides to the measurement of the problem for the purposes of emphasizing the areas in which activities might be most effective. Such measurement directs the planning of sound programs, provides the basis for needed legislation, and encourages the development of new standards through voluntary action. To be most meaningful, the suggested facts must be considered not only in themselves but also in relation to each other. These are by no means all of the facts and circumstances which may be classified for study nor does the order of their listing suggest their relative importance.

Data on area

Distribution of population by age, sex, and race.
Other descriptive information.

Data on fatal and nonfatal accidents

A complete description of the accident, the nature of the injury, and the consequences of the accident and injury will serve as a guide to measurement of the problem.

Age, sex, and race of the victim.
Activity at time of accident.
Probable cause of accident (personal or environmental factors).
Location on premises where accident occurred.
Time of day, week, or season.
Physical agent involved in accident.
Physical agent producing injury.
Manner and nature of injury.
Duration of disability.
Medical attention or hospitalization.
Wages lost, property damage, and other costs.
Medical and nursing costs.
Cause of death.
Place of death.

Data on other related factors

Sources of information such as victim, family, or neighbor.
Occupation of victim or head of household.
Physical condition of victim.
Type of home.
Location of home: urban, farm, or nonfarm.
Physical factors of general home environment.
Size of family.
Number of previous accidents.
Economic factors, if possible.
Other persons involved in accident.

For Home Accident Prevention Programs

ACCIDENTS in the home have become increasingly important as a cause of personal injury and loss of life; therefore, State and local health departments are recognizing the need for greater attention to home accident prevention. Since preventive programs are not yet being carried out to any great extent, techniques for evaluation of services are in an early stage of development. Because of the limitations in measuring certain phases of accident prevention, attention is directed here only to those items which are measurable.

While determination of program objectives does not fall within the scope of this guide, it is recognized that a long-range objective of home accident prevention is to lower the occurrence of accidental injuries, thus reducing morbidity and mortality.

It is essential to delineate that portion of the total objectives toward which the program is being directed at any one time. For example, one phase of the program may be directed toward reduction of accidents from certain causes, another toward prevention of accidents among certain population groups such as children or the aged, another toward reduction of accidents of designated severity, and still another toward increasing the awareness of accident-producing situations. Whatever the immediate focus of the program the objective should be clearly stated.

Determination of the steps toward achieving the long-term objective of a home safety program usually leads to the organization of the

program under the following general types of activity:

- Orientation and inservice training of the public health staff.
- General education of the public.
- Specific services to individuals and groups.

The job of home accident prevention belongs to all workers in the field of public health. At an early stage, program planners must enlist the help of the health educator, the statistician, and other staff service personnel. The staff should function as a part of the professional team throughout the stages of program planning, operation, and evaluation (1).

In evaluating any public health service it is necessary that there be a clear understanding on the part of all concerned regarding definition of terms used. Lack of such understanding leads to considerable loss of comparability of data and thus minimizes the value of evaluative studies. An effort is being made to standardize definitions and study is continuing through the Conference on Definitions of Accidents (2-4).

Statistical Information

Measuring Extent and Nature of Problem

For study and comparison, accident experience is best expressed in terms of both numbers and rates of death and, wherever possible, non-fatal injuries. Detailed facts about home accidents should be compiled and made available to all agencies concerned with public health.

services and the extent to which they have accomplished their purpose.

Staff orientation and inservice training

Measurable activities in staff training might include a series of lectures and demonstrations for local health department staffs by persons with special competence in home accident prevention. Material presented would include current statistics indicating the problem and reasons for integrating home accident activities with all public health work. This might be preceded and followed by written tests and field practice to determine the information level of the staff. Orientation of the staff to the use of techniques in reducing home accidents would be a part of this inservice training.

Public education activities

Public education by health authorities would include classes, lectures, exhibits, radio programs, and printed matter. This is a difficult area for which to establish objective indexes of accomplishment. However, a few suggestions for gauging increased knowledge and change in habit patterns might be measured by before and after quizzes, the use of checklists, and by counting requests for services and materials. Records of the number of requests will be more meaningful if they include a study of the characteristics of the groups being reached, with age, sex, and occupation indicated.

Because allied agencies are active in the educational phase of home accident prevention, it is difficult to pinpoint the effectiveness of health department work *per se* (10). The most valid study of the effect of materials used through mass media (radio, television, posters, pamphlets) might be made by the national agencies that develop the material (11, 12). Results of such evaluation should be available to local health departments for use in determining the educational medium to be used.

Another indication of the value of health department activities is in the number of second requests for speakers, literature, and consultation. This, of course, measures only requests for assistance, not the effect of it.

Specific services to individuals and groups

Recording of hazards, dangerous practices, and their correction (or continuation) may be included in activity reports, either routinely or by special arrangement. These records will provide evidence of home accident prevention services given to individuals or groups. To stimulate the correction of hazards, a health worker may distribute, for example, calendars for recording home accidents or Christmas tree tags with fire prevention instructions (13). He measures the effectiveness of these activities by counting the number of homes in which the calendars or tags are used. The number may not be the same as that of the homes to which the materials were sent.

Services to groups include such activities as lectures, program guidance, and panel participation.

The amount of time devoted by public health personnel in teaching home accident prevention should be measured for a short period. For example, periodic spot checks of the accident prevention content of the records of nurses and sanitarians may prove useful.

Records which need not be kept continuously but would prove valuable over a selected period of time concern referrals of individuals to specialized services and corrections effected. Suggested as examples are referrals of persons to clinics or private physicians because of poor vision or other physical handicaps, including congenital malformations and emotional disturbances.

A record of referrals and cooperative effort between groups active in home accident prevention adds meaningful evaluative information. The next logical step is the recording of the followup activities and their results. Records of referrals of environmental hazards may be those to:

- Gas companies for checking and correcting leakage, inadequate venting, or faulty operation.
- Electric companies for overloading, faulty equipment, or short circuits.
- Other fuel suppliers for inspection and correction of oil or coal furnaces and heaters.
- Municipal fire department for testing extinguishers, advice in correcting fire hazards.

Data on community knowledge and attitudes

Attitudes toward home accident prevention.

Knowledge of and attitude toward accident producing situations.

Possible ways of avoiding occurrence of similar accidents.

Suggested ways of avoiding recurrence of the accident.

Sources of health and safety information.

Because of the difficulty of measuring knowledge and attitudes little information is available. However, the bureau of maternal and child health of the New Jersey Department of Health has conducted a study designed to obtain data relating to these subjects (7).

Sources of Data

There are many limitations to be considered in determining sources of data for planning and administering a program. Questions which must be answered are (2): How reliable are the sources? Are they valid? Do they assure completeness of information?

Following are some suggested sources of data on fatal and nonfatal accidents.

Fatal accidents

- Death certificates supplemented by data collected with the National Office of Vital Statistics Home Accident Fatality Report or a similar epidemiological report.

- Hospital or emergency room reports if arrangements are made for the inclusion of detailed information about the accident.

- Reports of the medical examiner following inquiry into the circumstances of the accident.

Nonfatal accidents

- Sample surveys of homes.
- Surveys through schools, industries, service and social organizations.

- Hospital, clinic, and physician's reports, and poison information centers.

- Epidemiological reports collected by public health nurses, sanitarians, or others as a special project (8).

Measuring Effectiveness

Home accident prevention programs are not uniform; they vary with the nature of the problem and the staff available. Therefore,

the following suggestions need to be adapted accordingly.

Many of the items suggested for use in evaluation need not be collected and analyzed continuously. Periodic studies, especially of newly developed programs, are a valuable aid to program evaluation and revision.

Evaluation of home accident prevention programs has two major aspects:

- Evaluation of the entire program in relation to the long-range objectives.

- Evaluation of specific activities and services of the program in relation to the immediate objectives.

To be of maximum value, evaluation should be performed periodically. It should be followed by reexamination of the program in terms of both immediate and long-range objectives. Unsatisfactory progress indicates a need to replan the program and possibly to redefine objectives (9).

Long-Term Effect of Community Program

Collection and analysis of the following data may help gauge the effectiveness of an accident prevention program in achieving its ultimate goal:

- Trend of death rates from home accidents with respect to such factors as manner of injury, object involved, age, race, and sex.

- Indexes of change in nonfatal injuries by data from hospitals, emergency rooms, or, in some cases, from area surveys.

Caution must be used in drawing conclusions from the data. Evidence of change within a given area should not in itself be considered an adequate measure of the program's effectiveness. Comparisons with changes in a comparable area that does not have a preventive program help to strengthen the evidence regarding the effect of the program.

Effect of Health Department Services

A record of the number of activities, the time spent on them, and whatever measurable work is done does not necessarily indicate the health department's contribution to a communitywide program. It is necessary to supplement the records of the number of activities by some study of the content of the

Limitations on the Recreational Use of Domestic Water Reservoirs

CHARLES E. SMITH, M.D., D.P.H., and HENRY J. ONGERTH, B.S., M.P.H.

IN the public health sense, impounding reservoirs may be considered as falling into two general classes, those developed primarily for domestic water supply and those serving a whole spectrum of multipurpose uses. This paper applies only to reservoirs developed primarily for domestic water supply. In California these reservoirs are relatively few in number and represent only a small percentage of the total surface area of fresh water lakes in the State. However, their accessibility makes them especially convenient for recreational use.

In California, there is a conflict of interest in proposed recreational uses of domestic water supply reservoirs. Pressures of increasing population and increasing need for the limited water resources of the State result in an ever-growing appreciation that there must be maximum, and therefore multiple, use of our water resources. This multiple use may include recreational activities. People have more leisure time with more need for recreation than in the past, and, as cities grow larger, there is less

and less room for this recreation. For these reasons people interested in recreation desire to use all possible reservoirs and watersheds. The California State Board of Public Health officially expressed its position with respect to such use in a resolution which it adopted in 1955:

"The State Board of Health recognizes its responsibility for promoting the total health of the people of California and is cognizant of the beneficial role of adequate recreational facilities in the promotion of health. The board recognizes that in certain situations recreational use of water supplies under proper restrictions is feasible."

However, there is universal agreement that any possible damage to public health in the use of domestic water supply reservoirs must be prevented.

The California State Board of Public Health and the California State Department of Public Health neither compel nor prohibit the recreational use of domestic water supply reservoirs. Their stand is that this option is a local responsibility. In turn, the State's responsibility is to evaluate proposals for recreational use and to determine whether they provide sufficient safeguards to protect the public health.

There are two important factors to consider in this public health problem—hazards of disease transmission and esthetic considerations.

Transmission of Disease

We have considerable knowledge concerning risk of disease transmission, although it is admittedly incomplete. So far as we know, the

Dr. Smith is dean of the School of Public Health, University of California, Berkeley, and president of the California State Board of Public Health. Mr. Ongerth is a sanitary engineer and head of the water supply section of the California State Department of Public Health, Berkeley.

This paper was presented at the Conference on Recreational Use of Impounded Water held in Richmond, Calif., December 13-14, 1956, under the auspices of the department of conferences and special activities, University Extension, University of California.

• Municipal building department for advice in correcting structural defects.

• Manufacturers of household equipment, appliances, and furnishings.

Builders and contractors are among other groups offering a field for activity. In connection with new housing site inspections, recommendations for safe building and the number actually carried out provide a clue to the effectiveness of this field of work (14).

Studies

The 8 State and 4 local demonstration programs in home accident prevention, sponsored by grants from the W. K. Kellogg Foundation, have had accelerated experience in this field which may provide resources on special studies and service statistics (15). Baseline values of morbidity and mortality, activity counts, and service statistics of program activities were obtained by various methods in these demonstration programs. For additional reference and further information, health officers of the following departments or the directors of the home accident prevention programs may be contacted: local health departments—Cambridge (Mass.), Mansfield (Ohio), San Jose (Calif.), Kalamazoo (Mich.); State health departments—California, Georgia, Kansas, Kentucky, Maryland, Massachusetts, North Carolina, Oregon.

more chlorine is required for killing Cocksackie viruses than for killing *Escherichia coli*.

The newly recognized enteric cytopathic human orphan (ECHO) viruses also are excreted in feces. The role of these viruses in causation of diseases and their manner of spreading disease are as yet undefined although some appear to cause aseptic meningitis which may be confused with poliomyelitis.

Admittedly, poliomyelitis, Cocksackie, and ECHO viruses have never been proved to have produced waterborne epidemics and thus may only be theoretical hazards in water supplies. However, the virus causing infectious hepatitis is known to have caused waterborne outbreaks. The virus of this debilitating disease may badly damage the liver, frequently producing marked and severe constitutional symptoms with prolonged convalescence. The virus never has been cultivated nor have laboratory animals been found to be susceptible so data on its survival are not available. In the massive waterborne epidemic at New Delhi, India, in spite of the presence of a good treatment plant, 10,000 cases of hepatitis occurred.

We must recognize that the public's expectation of perfect performance of water treatment plants may be unduly optimistic. Man may err and equipment may fail. Even though water treatment facilities are provided, safeguards, care, and judgment must be exercised to insure that the capabilities of the installed facilities are not exceeded. We cannot accept the philosophy that it is unnecessary to concern ourselves with the quality of raw water, that all we need to do is spend enough for water treatment facilities to produce a safe and acceptable water.

In milk sanitation, major reliance for protection of milk supplies is placed on pasteurization, but the whole milkshed must provide barriers to contamination. Cows must be guarded against disease and the milk against dirt, manure, and human contamination. The final safeguard is pasteurization.

The same general principles must apply to the production of potable water. The watershed must be protected, insuring that the water will be kept as clean as possible along each step of the route. In addition, the water finally must undergo a degree of treatment consistent with the hazards to which it has been exposed.

Further comparison might be made with fire protection in communities. In the first place, we provide ourselves with regulations concerning construction of our manmade works so that fire hazards are reduced as much as is economically practical. Second, sufficient quantities of water and adequately manned fire-fighting facilities are provided to extinguish any fires which may occur. Finally, there is continuing surveillance and inspection. These examples illustrate the philosophy of providing factors of safety. It is not permissible so to lower factors of safety as to compromise the health and safety of the public.

Esthetic Considerations

The California State Department of Public Health recently had an inquiry from a person who asked why some of our water supply reservoirs were not open for swimming and bathing. In part, the department replied that the public is unwilling to accept such use of its domestic water supply reservoirs. The interest of the swimming recreationalists, on one hand, and the interest of the water consumer, on the other hand, are incompatible. Under such circumstances the conservative point of view should prevail. Therefore, it is more important to satisfy the esthetic senses of the thousands of water users than to develop unrestricted use of water supply reservoirs which seriously degrades the esthetic quality of the water.

The California State Board of Public Health, in whose hands the legislature has placed the responsibility for granting permits to water purveyors, is limited in its action by the State law which, in section 4016 of the Health and Safety Code, states: "If . . . the board determines, as a fact, that the water furnished or supplied or proposed to be supplied is such that under all the circumstances and conditions it is impure, unwholesome or unpotable or may constitute a menace or a danger to the health or lives of human beings, or the existing or proposed plants, works, system or water supply are unhealthful or insanitary, or not suited to the production or delivery of healthful, pure and wholesome water at all times, it shall deny the permit and order the petitioner to make changes as necessary to secure a continuous sup-

major disease potential in recreational use of water supply reservoirs is from improper disposal of human wastes, especially the feces, of those using the reservoir and watershed area. The inability to control all wastes leaves a potential hazard of some disease transmission.

Experience with water supply reservoirs in California now used for recreation has demonstrated that absolute control of human wastes has never been achieved. If control is lax, feces may be deposited directly in the water or on watershed lands. The hazard from the deposition of feces on land is obvious: falling rains and surface runoff will carry the material into the reservoir, pathogenic organisms may travel to the point of water intake from the reservoir, and, unless they are destroyed or removed by treatment, they may ultimately flow to the consumer.

When conditions exist which permit fecal discharges to enter raw water, it is important to know the fate of the pathogenic organisms. Using *Salmonella typhosa* as an example, the literature related to its survival in feces, soil, and water is of interest. Various conflicting reports have been summarized by Rudolfs and his co-workers from Rutgers University (1). From their summary, two things are clear: The bacteria may survive for periods as long as 100 days in feces or on soil, and the bacteria survive longer in pure water than in polluted water. This second observation is of critical importance to the waterworks industry, as pointed out by Taylor (2), who wrote: "Pollution of pure or purified waters at waterworks, in service reservoirs, or in mains is thus particularly dangerous, and the most stringent precautions are necessary to protect water prepared for delivery to consumers."

The clean water of many domestic water supply reservoirs and of all distribution reservoirs provides minimal biological competition for pathogenic micro-organisms which may contaminate it. Therefore, the opportunities for survival of pathogens are greater. On the other hand, in large impounding reservoirs and natural lakes, the factors of time, dilution, and sedimentation can enable recreational use of water without compromising the quality of the water as withdrawn for treatment. Water supply intakes must be protected by establishing a

closed area around them to prevent direct introduction of contaminating materials. Furthermore, care must be given to the location and design of the intake works to take advantage of the factors of time, dilution, and sedimentation.

Appropriate treatment must be provided for all surface water to guard against any pathogens which may elude the natural barriers. Fortunately, *S. typhosa*, and other pathogenic bacteria, are removable from water and are destructible. Investigations and experience have shown that complete water treatment, which includes filtration and postchlorination, can produce a satisfactory finished water from a contaminated raw water. However, we would stress that public health authorities have agreed that there must be bacterial limits for "raw" water whether receiving only chlorination or complete treatment. These limits are expressed in terms of the numbers of coliform bacteria which must not be exceeded if safe water is to be produced by treatment.

While it is agreed that, if not "loaded" too heavily, complete water treatment is adequate to produce a water free from bacteria which cause typhoid fever or other enteric diseases, the problem with respect to some parasites and viruses is not equally simple. Among the parasites we may mention *Endamoeba histolytica*, which causes amebic dysentery. Although amebic cysts normally are removed by filters they are difficult to destroy by chlorine when this is the only treatment employed.

The viruses present another challenge to water safety. Filtration is much less effective in removing viruses than in removing bacteria or parasites (3, 4). While poliomyelitis virus is usually spread by contact between infected and uninfected individuals, it is often present in the feces of healthy persons and has frequently been recovered from sewage. Fortunately, free residual chlorine rapidly inactivates it. The Cocksackie viruses also have been demonstrated in urban sewage. Most Cocksackie viruses do not cause disease, though one epidemic occurred in California during 1956. Like the typhoid bacillus, Cocksackie viruses have been shown to survive longer in unpolluted than in polluted water. They have survived as long as 47 days in river water. While chlorine will inactivate these viruses, from 7 to 46 times

Survey of Animal Ringworm in the United States

ROBERT W. MENGES, D.V.M., M.P.H., and LUCILLE K. GEORG, Ph.D.

RINGWORM in animals appears to be sufficiently common in the United States to present a potential public health problem. In August 1953 a study was initiated to determine which fungi were the common causes of ringworm in animals, to obtain data concerning the epizootiology of ringworm, and to determine the role of animals in the spread of infection to man. The plan and the objectives of the study have already been described (1), and reviews of the literature on animal ringworm have been published recently (2, 3). This paper summarizes the data accumulated during the 2-year period August 1953 through August 1955.

Veterinarians in 32 States assisted in the study, collecting specimens of hair from domestic, captive, and wild animals. In most of the wild animals, skin lesions were not present.

In the laboratory, all hairs were checked with a Wood's lamp for fluorescence, and, using 10 percent potassium hydroxide, a direct microscopic examination for fungus elements was made. Following this preliminary examination, the hairs were cultured on cycloheximide medium (4) and held at 25° C. for a minimum of 1 month before being discarded as negative.

Specimens of hair from 1,073 domestic animals were cultured. Dermatophytes were isolated from 277, or 26 percent. A summary of these results is presented in table 1. In addition,

hair specimens from 1,465 wild and captive animals were cultured, and dermatophytes were isolated from 243, or 17 percent (table 2). Thus, a total of 2,538 specimens of animal hair were cultured and dermatophytes were isolated from 520, or 20 percent. Figure 1 shows the distribution of the study animals and the number positive for ringworm.

Five different pathogenic organisms were identified among the animal isolates. These included *Microsporum canis* from cats, dogs, monkeys, and a chinchilla; *Microsporum gypseum* from dogs, mice, and rats; *Trichophyton mentagrophytes* from dogs, chinchillas, guinea pigs, a kangaroo, mice, rats, and an opossum; *Trichophyton equinum* from horses; and *Trichophyton verrucosum* from cattle and a burro. In addition, a variety of *M. gypseum* which was designated *M. gypseum* (red variety) was isolated from rats and mice. Dr. L. Ajello, of the Communicable Disease Center's Mycology Unit, describes this variety as a new species. A similar organism has been isolated from soil obtained from Idaho and Washington by Cooke (5), from Michigan by Ajello, and from Georgia by Menges (6).

Lesions were found in 408 of the 520 animals with ringworm. Scaling, circular lesions with alopecia were most common. The most common locations of the lesions were the head, the neck, and the leg.

The animal hairs were examined by culture, by direct microscopic examination, and by Wood's lamp for fluorescence. Of 290 cases which were positive by culture, only 117 (40 percent) were positive by direct microscopic

ply of pure, wholesome, potable, and healthful water."

My point in quoting this is to refer to the adjectives "wholesome" and "potable." The State board of public health holds that wholesomeness and potability also include esthetic considerations. When the water-consuming public considers that certain uses of sources of water are repugnant, then it is quite obvious that the water derived from these sources cannot be considered to be wholesome and potable. We must therefore recognize the feelings of the consumers, and we cannot permit uses of their water sources which are esthetically unacceptable. For this reason, the regulations which the State board of health adopted in December 1956 forbid recreational use involving "bodily contact" by man or animals.

Public Health Considerations

Wherever recreational use of water supplies is undertaken, there must be adequate control, for only with adequate control can such uses be tolerated. There must be assurance that the limits of contamination are not exceeded. Sanitary facilities adequate for the numbers of people in the area must be provided. The facilities must be convenient and they must be esthetically acceptable to the users. This includes their proper maintenance. Last but not least, there must be policing of the people in the area in order to keep their activities within limits consistent with the character of the area in which they are carrying on their recreational activities. The water purveyor must give assurance of this supervision. In addition, the local public health department having jurisdiction over the reservoir must provide appropriate public health supervision.

The State board of public health has considered matters of recreation on water supply reservoirs in the past. In 1951 it granted a permit to the city of San Diego to allow fishing on its reservoirs and in consideration of this action adopted a policy statement concerning recreation on reservoirs. At its meeting on December 7, 1956, the State board of public health formalized this earlier policy statement and adopted regulations on this subject. Problems described above have been

taken into account in the regulations, which call for (a) limiting the activities of people on the water supply reservoirs; (b) providing adequate sanitary facilities for use of the people; (c) maintaining these facilities; (d) policing the people in the area; and (e) providing an adequate degree of treatment of the water derived from these sources.

Conclusions

1. Water reservoirs may afford a healthful recreational resource for a community.

2. Because water is a vehicle of disease transmission, when a choice must be made between safe water or recreation, safe water must always prevail.

3. Recreational use of water supply reservoirs calls for a high level of supervision and control of people using the area to prevent their wastes from entering the waters.

4. Control of the recreational activities must be adequately budgeted and financed.

5. There must be adequate treatment of water derived from reservoirs.

6. Determination on the basic question of recreational use of water supply reservoirs must be made locally.

We must recognize that permitting such recreational activities constitutes a risk, but that the risk can be minimized to a reasonable and tolerable level if the conditions described are met.

examination and 46 (16 percent) by Wood's lamp. These results emphasize the value of cultures in diagnosing ringworm infections since *Trichophyton*-infected hairs usually do not fluoresce and infected hairs may be overlooked in direct examination.

Human Contacts

An attempt was made to gather evidence of the development of skin lesions in human beings in homes where infected animals were kept.

A history of such lesions was found in 59, or 31 percent, of 192 families in homes in which 252 infected dogs and cats were kept. Presumptive ringworm was found in 14 of 120 (12 percent) of the families associated with canine cases and in 45 of 72 (63 percent) of the families associated with feline cases. This information was obtained from the owners of infected animals by the veterinarians who attended the animals and by followup studies.

Thirty-four human outbreaks were thought to be caused by infected cats and only 12 out-

percent) of the *M. gypseum* cases were in rural areas.

Outbreaks of ringworm among groups of dogs were not common. Only one *M. canis* outbreak and two *M. gypseum* outbreaks were found in this study. All of the outbreaks occurred among litter mates.

Infections in Cats

Outbreaks of ringworm among cats were much more common than outbreaks among dogs. Ten outbreaks among cats were found in the survey; six of these occurred in breeding establishments.

Specimens of hair from 281 cats were cultured and *M. canis* was isolated from 125 (45 percent) of these. *M. canis* was the only dermatophyte isolated.

The age distribution of the cats is shown in table 4. Sixty-seven percent of the cats under 1 year of age had ringworm. Although the percentage of positive cats decreased with age, ringworm was found in cats of all ages.

There did not appear to be a marked difference in susceptibility to ringworm between the sexes. Fifty-seven (40 percent) of 144 males cultured, and 64 (49 percent) of 130 females cultured were positive. In the group under 1 year of age, 36 (68 percent) of 53 males and 34 (64 percent) of 53 females were positive. In the group aged 1-2 years, 13 (30 percent) of 44 males and 14 (34 percent) of 41 females were positive.

The data on breed and age were scanty, but there appeared to be a difference in the per-

centage of infections in purebred cats and in cats of mixed breed. This difference may indicate either that ringworm is apt to develop more readily among groups of cats confined in breeding establishments or that purebred cats are more susceptible to ringworm than other types of cats.

The peak months for the occurrence of ringworm among cats were September, October, and November. However, the numbers of cases are too few to admit of any definite conclusions. An analysis of the data according to season showed that 9 (21 percent) of 43 cats cultured in the spring were positive, 38 (37 percent) of 103 cultured in the summer, 67 (71 percent) of 94 cultured in the fall, and 11 (27 percent) of 41 cultured in the winter.

Only 2 (1.6 percent) of the 125 feline cases occurred in rural areas.

Infections in Cattle and Horses

Specimens of hair from 105 cattle were cultured and *T. verrucosum* was isolated from 21 (20 percent). *T. verrucosum* was the only dermatophyte isolated. The 21 cases were from 10 States and represented 14 herds of cattle.

The age distribution of the infected cattle was as follows:

| Age (years) | Number examined | Positive | |
|------------------|-----------------|----------|---------|
| | | Number | Percent |
| 2 and under..... | 45 | 18 | 40 |
| 3-4..... | 23 | 1 | 4 |
| 5-6..... | 20 | 1 | 5 |
| 7 and over..... | 6 | 0 | 0 |
| Unknown..... | 11 | 1 | 9 |

The ringworm cases occurred among both dairy and beef cattle, including Hereford,

Table 4. Age distribution of 281 cats infected with ringworm

| Age (years) | Number examined | Positive | |
|-----------------|-----------------|----------|---------|
| | | Number | Percent |
| Under 1..... | 109 | 73 | 67 |
| 1-2..... | 88 | 28 | 32 |
| 3-4..... | 42 | 16 | 38 |
| 5-6..... | 16 | 3 | 19 |

breaks, by infected dogs. The number of individuals involved in any one outbreak varied from 1 to 16; the total number of suspected cases was 107. The outbreaks occurred in 16 States (fig. 2).

Infections in Dogs

Specimens of hair from 641 dogs were cultured; 127 dogs (19.8 percent) had ringworm. *M. canis* was isolated from 77 (12 percent), *M. gypseum* from 46 (7.2 percent) and *T. mentagrophytes* from 4 (0.6 percent). *Keratinomyces ajelloi* was isolated from a 4-year-old male fox terrier from New Jersey with suppurative lesions on its head. *K. ajelloi*, however, has not been proved to be a pathogen.

Thirty-nine percent of the dogs under 1 year of age were positive for ringworm (table 3). This percentage decreased with age; only 1 percent were positive in dogs 7 years of age and over.

There did not appear to be a marked dif-

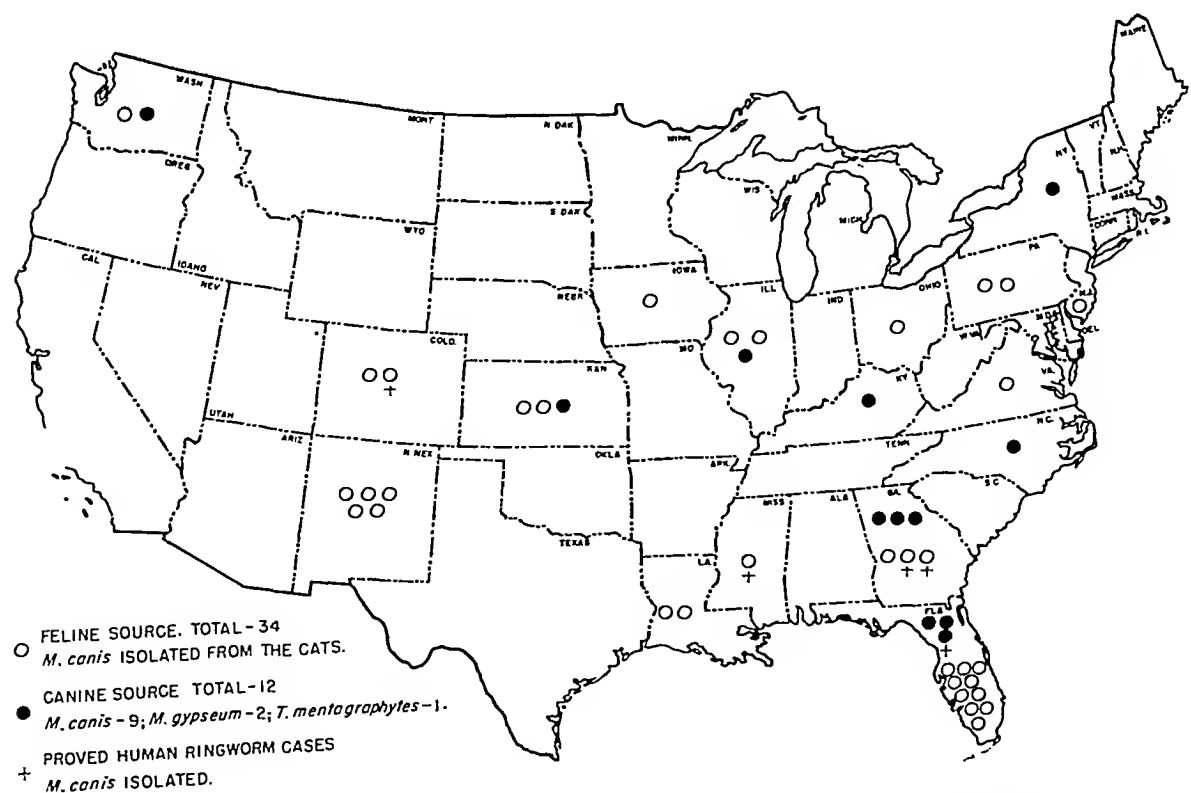

ference in susceptibility between the sexes; 78 (23 percent) of 342 males and 49 (17 percent) of 281 females were positive.

The data on breed group and age were too scanty to determine definite differences in susceptibility to ringworm; however, the data indicated that all breed groups were involved. Breeds were grouped according to the American Kennel Club classification. In the groups aged 1 and 2 years, the percentages positive were quite similar, possibly indicating that the breed of the animal is not an important factor in susceptibility to infection.

Twenty-two (14 percent) of 152 dogs cultured in the spring were positive, 43 (19 percent) of 227 cultured in the summer, 35 (22 percent) of 159 cultured in the fall, and 27 (26 percent) of 103 cultured in the winter. January was the peak month, with 10 (30 percent) of the 33 cultures positive.

Only 14 (11 percent) of the 127 canine cases of ringworm were found in rural areas. Six (7.7 percent) of the *M. canis* cases and 8 (17.3

Figure 2. Distribution of 46 outbreaks of suspected cases of ringworm in man associated with cases of ringworm in dogs and cats, August 1953 to September 1955.

dents. Because of their ubiquity and abundance, rodents would constitute a more likely source of human infection than the occasional infected dog or other farm animal.

Second to *M. canis*, *M. gypseum* appears to be the most common cause of ringworm among dogs in the United States. Verification of 46 cases during the 2-year period of this survey was quite surprising since this type of ringworm had previously been thought to be rare in animals. The recently acquired knowledge that *M. gypseum* is a common soil saprophyte (11), however, suggests that infection should be common in animals. The supposed rarity of *M. gypseum* infections is probably due to the fact that cultures are seldom made from animals suspected of having ringworm.

Summary

In a survey of domestic, captive, and wild animals for ringworm, dermatophytes were isolated from 520 (20 percent) of the 2,538 hair specimens cultured. The organisms commonly isolated were *Microsporum canis* from cats, dogs, monkeys, and a chinchilla; *Microsporum gypseum* from dogs, mice, rats; *Trichophyton mentagrophytes* from dogs, horses, chinchillas, guinea pigs, mice, rats, a kangaroo, and an opossum; and *Trichophyton verrucosum* from cattle and a burro. Data are presented concerning the frequency of skin lesions, method of diagnosis, and the epizootiological aspects of canine and feline ringworm. The results in-

dicade that ringworm is a common disease among animals in the United States.
